Pancreatic Enzymes in the Blood.—The pancreatic enzymes, *amylase*, and *lipase*, are found in the blood serum of normal individuals. The normal serum amylase is 80-200 units (Somogyi), and lipase is 85-205 units. The blood amylase level is markedly raised in acute pancreatitis, particularly in the early stages of the disease, and it continues to remain high, usually for a period of 24-48 hours, when it generally returns to normal or subnormal levels, but it may remain elevated for several days. After that time has elapsed a normal serum amylase is of little diagnostic value in ruling out the presence of this condition. The serum lipase is also increased in acute pancreatitis; it, too, becomes elevated early, but it remains at a high level for several days longer than does the amylase. In our experience the serum amylase level has proved to give the more reliable diagnostic information. The serum amylase level of the blood should be estimated daily in any cases suspected of pancreatitis in order to note any transient elevation, should it occur. It should also be estimated daily in proved cases of acute

pancreatitis, as it helps to follow the course of the disease.

Pancreatic Enzymes in the Urine.—The levels of *urinary amylase* and *lipase* are usually increased in acute pancreatic disease, but the estimation of the urinary enzymes lacks much of the accuracy and specificity of the blood serum findings.

Pancreatic Enzymes in the Peritoneal Exudate.—The amylase level of the peritoneal exudate closely parallels that of the serum. Abnormal values, however, can sometimes be obtained somewhat earlier than in the case of the blood serum. A sample of peritoneal exudate is quite readily obtained by needle aspiration.

Fig 314—The serum amylase levels in four cases of acute pancreatitis. The drop to a normal range in three of the patients was coincident with an improvement in their clinical condition.

Serum Calcium.—The estimation of the blood *serum calcium level* is desirable in cases of acute pancreatitis, as the deposition of calcium, which forms, with fatty acids, the calcium soap of fat necrosis, causes a fall in the serum calcium. A serum calcium level below 7 mg/100 ml is indicative of a major degree of pancreatic damage and fat necrosis, and, for the most part, gives evidence of a very serious prognosis. The serum calcium should be followed daily during the course of the disease, so that measures can be taken to correct a calcium deficiency, should it occur.

Serum Bilirubin.—A slightly elevated *serum bilirubin* is not uncommon during the early

phases of acute pancreatitis. However, clinical jaundice is unusual.

Blood Sugar.—*Hyperglycemia* is frequently found in acute hemorrhagic and acute edematous pancreatitis. This derangement in carbohydrate metabolism is usually transient in nature and is found early in the acute phase of the disease. However, it may persist following recovery, particularly in those cases in

Fig 315—Graph illustrating the comparative levels of amylase in the peritoneal exudate and serum in a case of acute pancreatitis.

Fig 316—The serum calcium levels in four cases of acute pancreatitis. The values tended to become normal in 6-7 days following the onset of the disease. No extra calcium was administered in these cases.

which marked pancreatic destruction has occurred. It is estimated that 10-15% of patients who recover from severe pancreatitis will be left with an impairment of their carbohydrate metabolism. As in the case of the serum calcium, the blood sugar levels should be estimated daily and insulin should be administered if a high blood sugar persists.

Glycosuria commonly accompanies the hyperglycemia

Hematologic Findings.—The white blood cell count tends to be elevated in acute pancreatitis (15,000-18,000). This elevation is partly due to the pancreatic disease and partly due to the accompanying hemoconcentration, which so frequently occurs in this condition. Marked leukocytosis does not as a rule occur, except in the case of suppuration which may follow acute pancreatitis or pancreatic injury. If hemorrhage into the pancreas is severe, the

Fig 317.—The fasting blood sugar levels in three cases of acute pancreatitis. The values remained high for some days. No insulin was administered in these cases.

Fig 318.—The glucose tolerance curve of a patient who had marked hyperglycemia. This observation was taken after the patient had recovered from the acute phase of the disease.

Fig 319.—The daily serum levels of sodium and chloride in a case of acute pancreatitis. The fall is not great, as this patient was treated with sodium chloride solutions, which undoubtedly prevented serious depletion of these ions.

Fig 320.—The daily serum potassium levels in a case of acute pancreatitis. Note the return to a normal range following the administration of parenteral potassium.

red cell count and hemoglobin levels will fall; however, the hemoconcentration due to the accompanying shock usually masks these signs of anemia. The packed cell volume may give evidence of this anemia and is a more accurate and useful test than the estimation of the hemoglobin level.

Serum Electrolytes.—The prolonged and copious vomiting of acute pancreatitis leads to rapid dehydration of the patient. A low level of serum sodium, chloride, and potassium is commonly found in the severe case. The serum levels of these ions should be measured daily and even more frequently in the early and acute phase of the disease, so that any electrolyte deficit may be prevented or corrected.

Duodenal Drainage.—Examination of the aspirated duodenal contents for the presence of pancreatic enzymes, particularly following hormonal or vagal stimulation, will give information regarding the external secretion of the pancreas. The administration of secretin in a patient with pancreatitis should result in a decreased output of the enzymes amylase, lipase, and bicarbonate ion. In contradistinction to the decreased enzyme output of the pancreas, the flow of bile is increased by the secretin injection.

The site of pancreatic lesions in *jaundiced patients* may at times be localized by the use of secretin. If after the injection of secretin both the pancreatic and the bile responses are absent or reduced, this is evidence of obstruction of the biliary and pancreatic ducts which is due to a lesion in the head of the pancreas. If, on the other hand, the pancreatic flow is normal with a decreased biliary response, the lesion is in the extrahepatic biliary system and not in the pancreas. If the pancreatic and biliary flows are normal following secretin injection, the probability is that the cause of jaundice is intrahepatic or hepatocellular. Absence of these enzymes is indicative of decreased pancreatic function and occurs in such diseases as chronic pancreatitis. Cytologic studies of aspirated duodenal contents may help in the diagnosis of carcinoma of the pancreas.

Examination of the Stool.—This is of value in diagnosis of chronic pancreatic in-

sufficiency. In such cases the stools are bulky, pale, and contain large amounts of *undigested fat*, starch, protein derivatives, and carbohydrate, due to lack of pancreatic enzyme digestion. The measurement of undigested fat in the feces is carried out after the patient has been placed on a fixed high fat diet for 3 days (Schmidt diet). The normal values of undigested fat in the stool is 7.3-27.6% of dry weight, and anything over that amount is significant.

The stool fat content may also be measured by radioactive isotope studies, using fat labelled with I^{131} . The fecal excretion of I^{131} is higher in patients with pancreatic disease. Excretion can be reduced by the oral administration of pancreatin. Occult blood may occur in carcinoma.

Fig. 321—Sentinel loop in a case of acute pancreatitis 8 hours after onset of symptoms

Urine.—The estimation of urinary enzymes, bile, and sugar is helpful in the diagnosis of pancreatic disease and has been previously discussed.

X-ray Examination.—In *acute pancreatitis*, a plain film of the abdomen will frequently show isolated distended loops of small bowel, usually containing fluid levels and most commonly situated in the upper midportion of the abdomen. As the disease progresses, the x-ray of bowel characteristic of a paralytic ileus. examination shows many large distended loops

Fig 322—Gas and fluid levels in the small bowel in acute pancreatitis. The barium was administered in an attempt to show the enlargement of the duodenal loop.

Fig 323—Diffuse pancreatic lithiasis. Note the location of the pancreas at the level of L1 and L2.

There may be a haziness or obliteration of the psoas shadow, separation of the stomach from the colon by an opaque mass, and occasionally a pleural effusion.

Pancreatic lithiasis and calcification in the gland parenchyma can be seen in the plain film. This calcification lies at the level of the bodies of the 1st and 2nd lumbar vertebrae and is best demonstrated by an oblique rather than an anteroposterior view.

The *pancreatic ductal system* may be visualized during laparotomy by the injection of

the duodenum. The development of a pancreatic abscess or pseudocyst of the pancreas can also be demonstrated by this method.

The x-ray diagnosis of *carcinoma* of the pancreas is difficult. It is accomplished by the use of contrast media introduced into the stomach and duodenum. The following points should be observed in barium studies of the stomach and duodenum:

1. The duodenal folds may be flattened where the tumor presses on the duodenal wall. At times there may be gross evidence of extrinsic pressure

Fig 324—Carcinoma of the head of the pancreas. Note the widening of the duodenal loop, the partial occlusion of the duodenum, and the upward displacement and compression of the stomach

radiopaque media into the pancreatic ducts and by subsequent x-ray examination. Occasionally the pancreatic ductal system will be visualized during routine cholangiography.

A barium meal may give confirmatory diagnostic evidence of acute pancreatitis if the patient is not too ill for this examination. There may be upward displacement of the stomach, widening of the duodenal loop, and obliteration of the normal mucosal pattern of

2. The reverse or inverted 3 sign is seen in growth of the head of the pancreas in the region of the common bile and main pancreatic ducts.
3. There may be widening of the duodenal loop by an enlargement of the head of the pancreas.
4. Obstruction of the duodenum occasionally occurs.
5. Obstruction of the common bile duct may be visualized by the use of intravenous cholangiographic methods which will demonstrate a block in the distal portion of the common bile duct. The use of this method is not successful in the case of the jaundiced patient.

Pancreatic cysts may be demonstrated by x-ray by the marked displacement of the stomach and transverse colon that frequently occurs.

damage to other abdominal viscera. The management of associated pancreatic necrosis or fistula formation will be taken up under the individual sections.

Pancreatic Biopsy.—At times it is impossible to make a positive preoperative diagnosis of pancreatic disease. The main problem is that of the differentiation between chronic pancreatitis and carcinoma. Exploratory laparotomy and pancreatic biopsy is, under these circumstances, a necessary procedure. It is important to obtain a representative piece of pancreas, and care must be taken that tissue from deep within the gland substance be included in the sample as the surface cells of the pancreas may not reveal the nature of the pathologic change. Such a deep biopsy may be taken with relatively little risk of fistula development in cases of pancreatic fibrosis or carcinoma as there is very little functioning glandular tissue and there is marked ductal occlusion. It must, of course, be realized that the tissue interpretation is difficult and a negative report for cancer does not always exclude malignancy.

INJURIES OF THE PANCREAS

Serious injuries of the pancreas are rare. When they occur, they are commonly associated with trauma to other intra-abdominal organs. They are caused by stab or gunshot wounds, underwater blasts, and severe contusions of the abdominal wall. Not infrequently minor injuries to the pancreas occur during the course of operative procedures in the upper abdomen, such as gastrectomy for duodenal or gastric ulcer, operations on the common bile duct, and splenectomy.

Occasionally pancreatic necrosis will follow a severe pancreatic injury. Pancreatic abscess, fistula, or cyst formation not infrequently develop following such injuries.

The clinical picture is that of a patient with an abdominal wound or other injury that manifests an unusually severe degree of shock. However, the diagnosis is seldom made prior to surgical exploration.

Treatment.—The treatment of serious pancreatic trauma includes the control of the associated shock and blood loss. Early operation is necessary in order to assess and repair any

ACUTE PANCREATITIS

There are two commonly recognized types of acute pancreatitis: (1) acute pancreatic necrosis or hemorrhagic pancreatitis; and (2) acute edematous pancreatitis. It is not definitely known whether or not these are separate diseases or whether they are different degrees of the same condition, but it seems most probable that the latter concept is the more correct. Acute pancreatic necrosis, although less common than the edematous variety, constitutes the more serious problem as regards treatment, morbidity, and mortality.

Etiology.—Although great progress has been made in the diagnosis and treatment of acute pancreatitis, the etiology of this disease is still somewhat obscure. The following classification indicates the numerous factors which may be the cause of this condition.

Etiology and Pathogenesis

- A Infectious Factors
 - 1 Viral, e.g., mumps pancreatitis
 - 2 Bacterial
 - a By direct spread from a contiguous infected gall bladder
 - b By lymphatic spread from an infected appendix
 - c By hematogenous spread
- B Noninfectious Factors
 - 1 Reflux of
 - a Bile—the "common channel" theory, as a result of
 - stone impacted at the ampulla
 - or spasm of the sphincter of Oddi
 - 2 Obstruction of pancreatic ducts due to
 - a Squamous metaplasia of the duct lining
 - b Pancreatic calculi
 - c Edema of the duct wall (often associated with the consumption of alcohol)
 - d Tumor
 - e Extrinsic pressure, e.g., duodenal diverticulum
 - 3 Trauma (known to give rise to certain cases of pancreatitis)
 - 4 Local vascular factors
 - a Rupture of a vessel
 - b Occlusion of arterial supply from thrombosis or embolism (including the possibility of fat embolism) or capillary thrombosis as a result of a sensitization reaction (Arthus phenomenon)

- 5 Nutritional and metabolic factors supported by experimental work of
 - a Coffey—patients with hyperlipemia and pancreatitis
 - b Kahser—d,l-methionine production of pancreatitis
 - c Hsieh—importance of collagenase, an enzyme present in inactivated pancreatic juice
 - d Alcohol
 - e Schwartzman reaction
- 6 Associated gall bladder disease

Pancreatitis of Infectious Origin

Occasionally the disease may be due to bacteria carried by the blood or lymph stream or in regurgitated bile. However, in most cases it would appear that any degree of infection follows only because of the secondary invasion of bacteria in the devitalized tissue of pancreatic necrosis.

There is an increased incidence of acute pancreatitis associated with typhoid fever and scarlet fever, and it has been reported that the Coxsackie virus has been isolated from patients with acute pancreatitis.

Pancreatitis of Noninfectious Origin

Although the etiology of acute pancreatitis is obscure, one factor seems to be present in all cases of the disease, whether occurring clinically or produced in the experimental animal. This essential factor is the escape of activated pancreatic enzymes from the ducts and acini into the pancreatic stroma and thence into the adjacent tissues. The release of these activated enzymes causes the local inflammation and necrosis, and their subsequent absorption into the blood stream probably plays a part in the profound systemic effect associated with the disease. It is probable that there is more than one mechanism enabling the escape of these activated enzymes into the unprotected gland tissue, the most likely being a blockage of the pancreatic ductal system which may be due to a stone in or edema of the ampulla of Vater, hyperplasia of the ductal epithelium, edema or tumors of the pancreatic duct or ampulla, or an extrinsic pressure factor. Experimental pancreatic duct occlusion will cause pancreatitis following the administration of secretin. The most likely sequence of events is that a regurgitation of activated enzymes

causes a mild inflammatory change. This is similar to the picture encountered in edematous pancreatitis.

Pancreatic necrosis then occurs as the result of a superimposed etiologic factor, probably vascular occlusion. The occlusion of vessels in the presence of inflammation results in necrosis. This vascular occlusion may be due to venous stasis caused by pressure on the vessels by the swollen and edematous pancreas, from vessel spasm, or from fat embolism. The site of the occlusion is probably capillary. The capillary wall breaks down, allowing a mixture of blood with pancreatic juice which produces a toxic substance capable of pancreatic digestion.

The role of the common channel has still not been proved. This anatomic abnormality frequently occurs in patients with pancreatitis and often has been found in autopsy specimens. However, it seems that there must be another factor in addition to the common channel required to produce the disease complex, namely, the factor of obstruction.

The pressure in the pancreatic ducts is 300-500 ml. of water, and it would be necessary to produce a pressure of 500 ml. of water in the biliary tree to cause a bile reflux; even if this does occur, it is unlikely that the pressure in the ducts is sufficient to cause exudation of pancreatic juice.

New impetus to the common channel theory has been given by the work of Elliott et al., who have shown that equal parts of bile and pancreatic juice, incubated for 14-48 hours at 37° C. and injected at low pressures into the pancreatic ductal system, will cause acute hemorrhagic pancreatitis.

Pancreatitis is frequently associated with biliary tract disease. In a series at the Royal Victoria Hospital this was found in 90% of cases. The diseased gall bladder may cause reflux of infected bile into the pancreatic duct, but this has not been proved. Nor has it been proved that gall bladder disease is infectious in origin. Whatever the real relationship, a high incidence of gall bladder disease with pancreatitis has been repeatedly shown.

Pancreatitis has also been found to be associated with lipid metabolism derangements

sential jaundice hyperlipoidemia can be found to precede pancreatitis in some cases.

Pancreatitis can also be produced by the administration of ethionine, which is an amino acid antagonist of methionine. This amino acid interferes with protein metabolism, causing a degeneration of the pancreatic cells.

Alcohol.—Consumption of alcohol is frequently associated with pancreatitis, either acute or chronic. Just how alcohol is involved in this disturbance is problematic. It may act through an associated dietary insufficiency, chiefly protein, which causes pancreatic cell degeneration; it may cause edema of the ampulla of Vater, leading to pancreatic duct obstruction; it may be that the vomiting of acute alcoholism causes a pressure reflux of duodenal contents into the pancreatic ducts, it may also be that alcohol has a specific toxic effect on the pancreatic cells; or it may cause the liberation of large amounts of secretin which increases the pancreatic flow against a partially obstructed duct.

Acute Hemorrhagic Pancreatitis

Pathology.—The pancreas is enlarged and is usually soft and friable, particularly in the fulminating types of the disease, although the gland may be firm in the milder forms. There are hemorrhage, marked edema, and necrosis of the pancreatic tissue. These changes may be confined to one part, e.g., the head or tail, or may involve the entire gland. It is our impression that when the tail is involved, the pain in the left hypochondrium is more pronounced. The yellowish white spots of *fat necrosis* occur on the surface of the pancreas or on the adjacent peritoneum and viscera. Usually these areas are pinhead or match-head in size but can be much larger and very widespread in the severe case, having been seen in the pericardium and mediastinum in some cases which have come to autopsy. This condition of fat necrosis is not a necrotic process at all but is the result of a chemical change caused by action of the pancreatic enzyme lipase, which acts on the neutral fat in the body, splitting it into glycerol and fatty acids. These fatty acids combine with the ionizable body calcium to form an insoluble calcium soap, which, when precipitated, constitutes the characteristic lesions.

A varying amount of blood-stained fluid is found in the peritoneal cavity; the lesser peritoneal sac may be completely filled.

Clinical Features.—Acute pancreatitis usually occurs in middle-aged patients, most commonly in the obese and overindulgent male, although it does occur in young and otherwise healthy adults. There is a frequent history of gall bladder dyspepsia and previous acute attacks of similar nature to the present one. There is a frequent history of a recent heavy meal or a large intake of alcoholic beverage. The disease has an acute onset and is accompanied by pain, which is most marked in the mid or left epigastric region but may extend to either the left or right subcostal regions or may even be referred to the left subscapular, left lumbar, or left shoulder regions. Rarely, the pain may be in the right shoulder and the right subcostal region.

In the severe cases of hemorrhagic necrosis the patient exhibits all the signs of shock, with a rapid pulse, cold clammy skin, cyanosis, and low blood pressure. There is evidence of marked physical and mental distress. Vomiting is severe and persistent, and the vomitus may be blood-tinged. Dehydration is early and severe. Abdominal tenderness is present, but it is not marked and is usually maximum in the left epigastric region. There is rigidity of the abdomen, most perceptible in the epigastric region, but it is not so pronounced as, for example, the abdominal rigidity in perforated peptic ulcer. Rectal examination reveals no tenderness. This fact helps to differentiate this condition from perforated peptic ulcer, where rectal tenderness is usual, because of the acid peptic juice which runs down into the pelvis along the paracolic gutters. There may be areas of bluish discoloration in the flanks and in the umbilical region, due to extravasated blood and pancreatic enzymes. This discoloration is evidence of a very severe form of the disease but, as it occurs late, it is of little or no help in diagnosing either the mild varieties or the early stages of the severe form. Aspirated fluid from this discolored area has a high amylase content.

Acute Edematous Pancreatitis

Pathology.—As is evidenced by the name, the pancreas is swollen and edematous. There

may be small areas of hemorrhage, but there is no widespread gangrene or necrosis of the gland itself. Fat necrosis of moderate degree occurs in the usual areas

Clinical Features.—The clinical features of acute edematous pancreatitis are similar in nature, but are less severe than those of pancreatic necrosis. Again, as in the hemorrhagic variety, there is a frequent history of gall bladder dyspepsia and previous acute attacks of a similar nature to the present one. The pain and the rigidity are much less pronounced, and shock is not common. The condition is frequently confused with acute cholecystitis.

Diagnosis.—The signs and symptoms of the severe form of the disease are typical. However, the diagnosis of the edematous variety frequently requires laboratory confirmation. The serum amylase and lipase are elevated, particularly in the early stages of the disease. The level of the blood sugar is raised, while that of the serum calcium is depressed. The serum bilirubin is slightly elevated. There is a moderate leukocytosis and a raised hematocrit. Survey films of the abdomen often show dilated loops of bowel. Glycosuria may be present (See Laboratory Aids in Diagnosis.)

Differential Diagnosis.—Acute pancreatitis must be differentiated from acute cholecystitis, perforated peptic ulcer, early intestinal obstruction, acute appendicitis, mesenteric thrombosis, acute gastritis, and coronary artery occlusion.

Treatment of Acute Pancreatitis

The plan of treatment of acute pancreatitis is directed toward the support of the patient and the prevention of spread of the disease process. Surgical intervention is not indicated in the uncomplicated case of acute pancreatitis.

The treatment of edematous pancreatitis is the same as that of the acute hemorrhagic type. However, heroic supportive measures are rarely necessary in the milder form of the disease. There are eight aspects of the plan of treatment:

1. The relief of pain
2. The treatment of shock
3. The treatment of dehydration
4. The prevention of further autodigestion of the pancreas

5. The correction of secondary metabolic derangements

6. The prevention of secondary infection

7. The removal of the gall bladder

8. Dietary control

The Relief of Pain.—Very severe pain must be relieved. Occasionally it is so severe that analgesics such as morphine or Demerol must be administered in full therapeutic dosage. However, as both these drugs cause an increase in duodenal irritability and spasm of the sphincter of Oddi, they are theoretically contraindicated as this sphincter spasm may contribute to the disease process by promoting bile reflux into the pancreatic ducts.

Milder analgesics such as codeine or acetylsalicylic acid may be sufficient in some cases. The barbiturates and the nitrates are useful in the relief of pain because of their smooth muscle-relaxing properties.

Paravertebral procaine nerve block from T4 to T10 or an epidural or a splanchnic block will relieve pain, even in the most severe cases. This method of pain relief has a second virtue in that it will tend to relieve any pancreatic ischemia by blocking out the vasoconstrictor nerve fibers of the pancreatic vessels.

The administration of analgesics and the employment of paravertebral or splanchnic block should be continued for as long as the presence of pain requires their use. As a rule, one procaine injection is sufficient and need not be repeated. The milder forms of pain-relieving drugs are generally all that are required once the acute phase of the disease has passed.

The Treatment of Shock.—The occasional severe shock in acute pancreatitis is treated by the usually accepted antishock measures, the mainstays of which are intravenous infusions of whole blood and blood plasma. Plasma substitutes may be used as an initial step or if the blood and plasma are not available. Tissue anoxia should be minimized by the administration of oxygen, either by nasal catheter or by an oxygen tent.

ACTH, cortisone, and compound F are useful in those cases of fulminating hemorrhagic pancreatitis which develop severe shock and which do not respond to antishock measures. In such patients we have found that marked

improvement may follow the use of those drugs.

The following dosage schedule should be used: The quick-acting ACTH is given in amounts of 10-25 mg. dissolved in a liter of intravenous fluid. This quantity is given over a period of 12 hours, or intravenous cortisone at the rate of 10 mg./hour. This dose should be repeated every 12 hours for the ensuing 48 hours, after which it can be superseded by intramuscular cortisone. At the same time as the initial dose of ACTH, the slower-acting cortisone, in a dose of 300-400 mg., should be given intramuscularly. This dose is followed in the second 24-hour period by another injection of 200-300 mg. The cortisone is then repeated daily, reducing the dose somewhat each day, until it is finally discontinued after 5-6 days. Oral cortisone is not practical in these cases because of the persistent vomiting and the therapeutic use of continuous gastric suction.

Repeated eosinophil counts should be done when using ACTH and cortisone therapy, as it has been found that when the eosinophil count does not fall following the use of these drugs it is an indication that the dosage level is inadequate. The dose should then be increased until an eosinophil response is obtained.

Once the immediate shock is controlled, further administration of blood plasma or plasma substitutes is not necessary unless an exacerbation of the acute pancreatitis occurs.

The Treatment of Dehydration.—Dehydration occurs early and is usually very severe. It is due to the prolonged and copious vomiting, the absence of fluid intake, the intraperitoneal loss of pancreatic juice, and the marked peritoneal exudate which occurs because of the irritation caused by released enzymes. In the later stages the developing paralytic ileus, with its large loops of adynamic bowel, which frequently contain many liters of fluid, contributes still further to the state of dehydration. There is, in all these cases, a combined depletion of both electrolytes and water, as large quantities of the acid chloride ion are lost in the vomitus and large quantities of the alkaline sodium ion are lost in the released pancreatic juices. Replacement therapy must therefore be planned and balanced, so that the correct pro-

portions of electrolytes are administered to make up these deficits. In the later stages of the disease the potassium ion should also be given to replace the intracellular ion deficit, which closely follows the original extracellular dehydration.

An indwelling urethral catheter is an important part of the fluid replacement program, as an accurate measure of the urine output is at all times most essential.

Once the marked dehydration has been corrected by vigorous treatment with a balanced electrolyte solution, the day-to-day fluid and electrolyte requirements of the patient who is taking no fluid by mouth and who is on continuous gastric suction must be maintained by a carefully calculated daily amount. This fluid must be given by parenteral and never by oral means during the period of gastric suction. Accurate fluid intake and output measurements must be continued throughout the entire course of the disease.

The Prevention of Autodigestion.—In order to prevent further outpouring of pancreatic enzymes from the damaged ductal system, certain measures can be taken to minimize pancreatic secretion. The neurogenic phase of the pancreatic secretion can be reduced by the administration of cholinergic blocking drugs such as atropine or Banthine which should be given in full therapeutic dosage until symptoms of overdosage of these drugs appear. Atropine and Banthine must be given by hypodermic or intravenous injection, as drugs are not absorbed from the gastrointestinal tract of a patient with acute pancreatitis, and in any event the therapeutic gastric suction prevents successful oral administration of any drug.

The hormonal phase of pancreatic secretion can also be minimized by measures which prevent the gastric contents from entering the duodenum. The best method of accomplishing this is by continuous gastric suction.

Oral fluids should be prohibited during the period of suction as they will only serve to increase gastric secretion, which will increase the production of secretin which, in turn, will further increase the liberation of pancreatic enzymes, thus adding to the neurogenic addition to the direct effect on the neurogenic secretion, the cholinergic blocking drugs, via their vagus effect, also decrease the flow of

gastric juice, thus helping, in this manner, to reduce the hormonal phase of pancreatic secretion.

Antienzymes have been used experimentally: quinine as an antilipase factor, soybean and S.F.S. (sodium formaldehyde Sulfoxylate) as antitypsin agents. A carbonic anhydrase inhibitor (compound 6063), has also been used. The results have not been particularly good, and these substances are not recommended for clinical use at present.

The continuous gastric suction should be maintained until all the biochemical abnormalities have returned to normal. On no account should this important aspect of the treatment be discontinued simply because the serum amylase level becomes normal. The use of the cholinergic blocking drugs should be continued well into the convalescent period. If the gall bladder is to be removed, these drugs should be continued until the patient finally recovers from the operation, which may be 6-8 weeks after the acute attack.

The Correction of Secondary Metabolic Derangements.—

Calcium Deficiency.—A low serum calcium level should be corrected by the administration of intravenous calcium salts. It is estimated that approximately 150 mg. of calcium ion should be given for every 1 mg. drop in the serum calcium level. Due regard, however, must be paid to the errors inherent in serum electrolyte estimations, e.g., hemoconcentration. This dose will not have to be repeated unless there is an exacerbation of the disease process leading to a second formation of fat necrotic areas. The precipitation of the areas of fat necrosis is an early and, so far as we know, a nonprogressive phenomenon, so that there is no necessity for the continued feeding of a calcium-hungry area, such as is found in the bones of a patient suffering from the post-operative tetany of hyperparathyroidism. In these cases calcium must be given daily for a considerable period of time, until the bone depletion has been corrected.

Careful attention must be paid to the fact that different salts of calcium contain very different quantities of the calcium ion, for example, calcium gluconate contains about 9% calcium, calcium lactate about 18%, and

calcium chloride about 36%. If, therefore, it is desired to administer 150 mg. of calcium ion, it is necessary to give the patient approximately 1.5 Gm. of calcium gluconate. The chosen quantity of calcium should be administered by a slow intravenous drip over a period of 3-4 hours. Those salts of calcium which contain a relatively large proportion of ionizable calcium, e.g., calcium chloride, are not recommended.

The continued use of parenteral calcium should not be necessary after the first 48 hours, unless there is an exacerbation of the disease. Once the patient takes food by mouth, the average normal diet contains sufficient calcium for his needs, so that it need not be added to his diet in the form of calcium salts or high calcium foods.

Hyperglycemia.—It is important that any severe and prolonged hyperglycemia be prevented by the administration of insulin. The insulin-producing Beta cells of the pancreas are susceptible to high blood sugar levels, and those islet cells which escape the initial injury of the pancreatic destruction may be permanently damaged should an uncontrolled hyperglycemia be allowed to persist. The blood sugar level should be controlled by small repeated doses of the quick response, short action crystalline insulin. Repeated estimations of the blood sugar are necessary in order to regulate the insulin dosage. Estimation of the urinary sugar is of little value in these cases as the vigorous intravenous therapy with glucose-containing solutions causes a glycosuria, even in the absence of impaired carbohydrate metabolism.

Insulin overdosage should be scrupulously avoided, as the vagus nerve, when stimulated by hypoglycemia, will cause an increase in the external pancreatic secretion.

It is believed that the conservation of islet cell tissue by the careful administration of insulin in these cases of acute pancreatitis, which show more than a transient hyperglycemia, will reduce the number of patients who develop diabetes subsequent to the pancreatitis.

If the acute pancreatitis has been severe, with marked tissue damage, the resultant hyperglycemia may be prolonged and even permanent. Careful dietary and insulin control

should be continued until the abnormal carbohydrate metabolic state becomes stabilized. This may take 2-3 weeks. A glucose tolerance curve should be carried out on all patients after they have recovered from the acute disease in order to diagnose any insipient diabetes.

The Prevention of Secondary Infection.—The development of early infection is not a problem in acute pancreatitis. However, later in the course of the disease, particularly if laparotomy and drainage have been carried out, infection with abscess formation may occur. This abscess formation may also arise via lymphatic drainage from the gastrointestinal tract, or it is remotely possible from regurgitated infected bile. Infection can be prevented by the avoidance of operation and by the program outlined above. A wide-spectrum chemotherapeutic agent should be used. Some of these agents have a theoretic advantage in that when given by mouth, they are secreted by the liver with the bile. This factor may help to prevent reactivation of the pancreatitis from infected bile if such a situation obtains.

The administration of the chosen chemotherapeutic agent should be continued for several days after the patient has a normal temperature and has otherwise recovered from the acute pancreatitis.

Removal of the Gall Bladder.—As chronic cholelithiasis and chronic cholecystitis so frequently accompany or precede acute pancreatitis, it is recommended that once the patient recovers from the acute attack, the diseased gall bladder should be removed. The optimum time for this procedure is 6-8 weeks following recovery. During this intervening time the patient should be kept on a modified acute pancreatitis regime, which consists of a low fat bland diet with atropine or Banthine and the prohibition of alcohol.

In patients in whom there is no demonstrable gall bladder disease or common duct obstruction, the gall bladder should not be removed. However, the patient should be carefully observed over a prolonged period so that if such disease does become detectable, suitable operative treatment may be planned.

Although the treatment of acute pancreatitis is not operative, occasions do arise when a

laparotomy is performed. Perhaps the diagnosis may be obscure or the abdomen may require opening for an associated disease, commonly acute cholecystitis. If the patient is not severely ill, a chronically diseased gall bladder may be removed at this time with perfect justification. If an acutely inflamed gall bladder is discovered, it is desirable that it be removed if at all possible. However, if the patient is extremely ill, drainage of the gall bladder may be all that can be safely performed. If a patient with acute hemorrhagic pancreatitis is subjected to laparotomy, it is doubtful whether any surgical procedure should be attempted except that an acutely inflamed gall bladder occurring in association with the disease may be drained.

So far as the common duct is concerned it should be explored in nearly all cases of elective cholecystitis associated with pancreatic disease. It may at times be explored in patients during an acute attack of edematous pancreatitis if the patient's condition is satisfactory. The common duct, however, should not be touched in cases of acute gall bladder disease associated with edematous pancreatitis or in the presence of acute hemorrhagic necrosis.

Dietary Control.—Once the intravenous feeding has been discontinued, the patient should be placed on a high protein, high caloric, and low fat bland diet. This food should be given in 5-6 small meals a day, which tends to prevent overloading of the stomach and resultant undue stimulation of the biliary and pancreatic systems. Alcoholic beverages should be prohibited.

Complications of Acute Pancreatitis

Complications are more usually found following the acute hemorrhagic type and include abscess and fistula.

The treatment of pancreatic abscess is surgical drainage and appropriate chemotherapy. The treatment of pancreatic cysts and fistula is discussed later.

As a sequel to the disease, impaired glucose tolerance or frank diabetes may occur which will require dietary or insulin control. There may also be an impairment in the production of pancreatic enzymes, leading to the bulky, pale stools of pancreatic insufficiency.

CHRONIC PANCREATITIS

It is still a matter of debate as to whether this condition is a disease in itself or a sequel of acute pancreatitis. The abnormality takes several forms, the most common of which is seen in the indurated pancreas which is frequently found at laparotomy, particularly when the conditions of chronic cholecystitis and cholelithiasis are present. This pancreatic induration probably does not cause symptoms which can be differentiated from those of the associated gall bladder disease. Specific treatment is not necessary, and removal of the gall bladder, in nearly all cases, ends the problem. More advanced chronic pancreatitis is much more serious. The chief symptom is severe and unremitting pain which frequently drives the patient to drug addiction. There is also evidence of chronic malnutrition, pancreatic insufficiency, and at times jaundice.

The third type is the so-called chronic relapsing pancreatitis, the usual pattern of which takes the form of irregularly recurring attacks of acute pancreatitis. The attacks increase in severity and frequency as the disease continues, until the picture is identical with the above-mentioned type of advanced chronic pancreatitis.

Pathology.—The pathologic picture varies from a minimal degree of fibrosis, which may be limited to one area of this gland, to a diffuse fibrous change of all the gland, with an almost complete destruction of the pancreatic parenchyma and obliteration of the ductal system. In addition to the fibrosis there may be calcification of the parenchyma, stones in the pancreatic ducts, or both.

Clinical Features—The diagnosis of chronic pancreatitis is difficult and can be proved only by operation and biopsy or at autopsy. Pain is a very common symptom; it is epigastric in position and tends to radiate to the back. This pain, however, is not pathognomonic of chronic pancreatitis and is not in any way a reliable diagnostic feature. When jaundice occurs it is of the typical obstructive type, and although pancreatic disease may be suspected to be the underlying cause, carcinoma of the pancreas cannot be excluded on clinical grounds alone. Diabetes or low sugar tolerance is not uncommon, and there may be signs of deficiency

in the external pancreatic secretions which is manifested by pale, bulky stools. There may be a decrease or absence of the pancreatic enzymes in aspirated duodenal contents. The levels of serum amylase and lipase may occasionally be elevated. Loss of weight is common if the disease has been established for a period of time. A plain x-ray of the abdomen may show pancreatic calcification.

Treatment.—This is both medical and surgical. Measures should be taken to ensure prohibition of food and drink which promotes a marked pancreatic response, e.g., fat, large meals, and alcohol.

Pancreatic ferments and insulin may be required if there has been marked glandular destruction. Anticholinergic drugs and alkalies may also be helpful.

The main form of treatment, however, is surgical. Selection of the type of procedure varies with the pathologic process, and the choice can frequently be determined by clinical and laboratory means.

There are six forms of surgical therapy.

1 Cholecystectomy for a diseased gall bladder and removal of stones from the common duct.

2 Relief of jaundice in those patients with severe pancreatic fibrosis producing occlusion of the common bile duct. This is accomplished by dilatation of the common duct and subsequent prolonged drainage or by biliary tract diversionary measures such as cholecystenterostomy, choledochenterostomy, or choledochoduodenostomy.

3. Operations which promote common duct drainage such as transductal or transduodenal division of the sphincter of Oddi or choledochoduodenostomy.

4 Operations designed to decrease pancreatic secretion, such as partial gastrectomy, vagotomy, and gastroenterostomy.

5 Operations on the pancreas itself which may be

a Removal of stones from the pancreatic ducts.

b Excision of the tail of the pancreas with subsequent retrograde drainage by anastomosis of the body of the pancreas and the pancreatic duct to a defunctioned loop of jejunum by a Roux-Y anastomosis.

c. Resection of the pancreatic head, i.e., pancreaticoduodenal resection

d. Total pancreatectomy

6 Procedures designed for the relief of pain such as splanchnicectomy, alcohol injection of the splanchnic nerves, or epidural injection with local anesthetic, followed by a subsequent injection of alcohol

Selection of Cases for Therapy.—

1. Cholecystectomy should be performed in every case of chronic pancreatitis if there is any evidence of gall bladder disease. The common duct should be explored at the time of the cholecystectomy.

2. The presence of jaundice always poses the problem as to whether or not cancer is present. A biopsy and frozen section is often very helpful in deciding this point

Chronic fibrosing pancreatitis causing common duct occlusion and jaundice is treated by diversion of the biliary stream by either cholecystenterostomy, choledochenterostomy, choledochoduodenostomy, or prolonged common duct drainage.

3. Division of the sphincter of Oddi is of value only when the pancreatic duct obstruction is at or near the sphincter. If the block is in the head of the pancreas, division of the sphincter will not benefit the condition. This form of treatment is best suited to chronic relapsing pancreatitis.

4 Gastric resection and vagotomy tend to minimize duodenal stimulation by acid chyme and thus prevent vagal stimulation of the pancreas. These procedures are of value only in chronic relapsing pancreatitis.

5 The choice of operation on the pancreas itself varies with the pathologic process. Pancreatic ductal stones are removed when palpable or when visualized in plain films of the abdomen or by pancreatic duct injection with contrast media

Retrograde drainage is feasible when there is stricture, metaplasia, or calcification in the head of the pancreas which can be decompressed by pancreatic intestinal anastomosis

Partial or total pancreatectomy may be carried out for marked fibrosis or calcification. This is a formidable procedure which should not be undertaken lightly.

6. As the nutritional problem following total pancreatectomy is difficult and the mortality of the operation is high, marked fibrosis causing intractable pain is probably best treated by the indirect approach of splanchnicectomy or epidural nerve blockage.

Specific Chronic Pancreatitis

Specific inflammatory conditions of the pancreas, such as those due to syphilis and tuberculosis, are rare. The treatment is that of syphilitic syphilis and tuberculosis.

Pancreatic Lithiasis

The etiology of this condition is unknown, but it is probably a sequel of acute or chronic pancreatitis. Pancreatic stones are similar to salivary calculi. They are usually multiple and lie in the larger ducts. Calcification of the pancreatic parenchyma also occurs, either in conjunction with pancreatic stone or by itself.

Clinical Features.—The clinical picture is almost identical with that of chronic pancreatitis. The pain, which may be very severe and debilitating, is deep epigastric in position and radiates to the back. Nausea and vomiting are fairly common. The patient may show signs of pancreatic insufficiency with sometimes diabetes or jaundice. X-ray of the abdomen will frequently demonstrate the calculi which are usually radiopaque. Calcification of the pancreatic parenchyma is also shown by this method

Treatment.—The treatment is surgical and consists of removal of the stone in cases where this is possible or pancreatic resection in those cases with diffuse calcification. As in ordinary chronic pancreatitis, bilateral splanchnicectomy will give relief of pain in some cases. Attention must be paid to insufficiencies of the pancreatic secretions.

PANCREATIC CYSTS

Pancreatic cysts are not common; the most frequently occurring variety is pseudocyst of the pancreas, which develops as a complication of acute pancreatitis or pancreatic injury. The following classification indicates the types which have been reported (Mahorner and Mattson).

- I. Cysts resulting from defective development
 - (a) cysts in infants
 - (b) cysts associated with polycystic disease of the kidney
 - (c) dermoid cysts
 - (d) inclusion cysts
- II. Cysts resulting from trauma
- III. Retention cysts
- IV. Neoplastic cysts
 - (a) cystadenoma
 - (b) cystadenocarcinoma
 - (c) teratomatous cysts
- V. Cysts resulting from parasites

Pathology.—Pancreatic cysts may occur in any part of the gland. They usually present above or below the stomach but may be below the colon, causing displacement of these organs; this can be demonstrated by x-ray.

Following are the three most common and most important cysts of the pancreas. (1) cystadenoma, (2) fibrocystic disease, and (3) pseudocyst

Clinical Features.—The clinical features of pancreatic cysts in adults are the same regardless of the exact nature of the cyst. There is frequently a history of acute pancreatitis or trauma to the abdominal wall or of abdominal operations. The majority of cysts, however, are not noticed until they form a readily palpable mass. In the later stages there is vague pain, loss of weight, nausea, and vomiting. Rarely jaundice occurs due to extrinsic pressure on the biliary system. Impaired glucose tolerance, diabetes, and insufficiency of external secretion may occur.

Cystadenoma of the Pancreas.—This is a large polycystic tumor with papillary projections from its columnar cell lining. It rarely gives rise to symptoms until it becomes large enough to cause pressure on the surrounding structures. Malignant forms occur. The treatment is surgical removal.

Fibrocystic Disease.—Fibrocystic disease of the pancreas occurs in infants and children. It is characterized by widespread fibrocystic changes in the pancreas, which are usually associated with similar changes in other organs, notably the lungs and kidneys. There is complete loss of external pancreatic secretion due to malformation of the ducts, which gives rise to the condition known as meconium ileus.

Treatment.—Laparotomy is usually required to relieve the intestinal obstruction. Pancreatic enzymes should also be given. The prognosis

is unfavorable because of the associated fibrocystic disease in other organs.

Pseudocysts or False Cysts.—These cysts are effusions into the lesser peritoneal sac which become sealed off by adhesions. Occasionally they contain blood because of small hemorrhages from the vessels either in the pancreas or the cyst wall. They occur following acute pancreatitis or trauma.

Treatment is excision of the cyst with anastomosis of the cystic remnant to the jejunum by a Roux-Y anastomosis. Sometimes this is not feasible because of technical difficulties, and a simple marsupialization of the cyst to the anterior abdominal wall is carried out. If this is done, it is recommended that a sphincterotomy be done at the same time and the patient be forbidden alcoholic beverages and placed on a low fat diet until the pancreatic secretion completely disappears.

PANCREATIC FISTULA

These fistulas may be internal or external. The diagnosis of the external variety is obvious, and it is the only one of clinical importance. There is a history of acute pancreatitis or surgical operation. There may be insufficiency of either the internal or external pancreatic secretions. In severe forms of the external variety, dehydration, due to loss of fluid and electrolytes, may occur. There is frequently a digestion of the skin of the abdominal wall in the early stages of external fistulas.

Treatment is excision of the fistula where possible or anastomosis of the tract to the gastrointestinal system.

TUMORS OF THE PANCREAS

The usual benign glandular tumors which occur elsewhere in the body are found in the pancreas, namely, adenoma, fibroma, and fibroadenoma. They rarely cause symptoms and are seen as incidental findings at laparotomy or autopsy. Two forms of tumors of the pancreas are of clinical importance:

1. Islet cell tumors
2. Adenocarcinoma

Islet Cell Tumors

Tumors of the islet cells are frequently associated with hyperinsulinism. They do oc-

cur, however, with no demonstrable change in carbohydrate metabolism and pass unnoticed unless discovered during abdominal exploration for other conditions or at autopsy. When hyperinsulinism is present, the symptoms are those of severe and recurrent hypoglycemia, which is manifested by sweating, flushing, pallor, dizziness, weakness, hunger, nausea, epigastric pain, syncope, and mental changes. A diagnosis of epilepsy or some circulatory abnormality is sometimes erroneously made in these cases. Hyperinsulinism can also be caused by a diffuse hyperplasia or hypertrophy of the islets of Langerhans. The symptoms are indistinguishable from those of islet cell adenoma.

Treatment.—Surgical removal of the hyperfunctioning tumor is essential. Occasionally a diffuse hyperplasia of the islet cells causes hyperinsulinism. In this case the treatment is radical subtotal resection of the pancreas. The results of excision of the pancreatic adenoma are good if irreversible mental changes have not occurred.

(See Chapter 13, *Surgery of the Endocrine Glands*.)

Carcinoma of the Pancreas

The only malignant tumor of clinical importance other than the islet cell carcinoma is adenocarcinoma. It has been more often encountered in recent years because of more accurate diagnosis and the growing awareness of this condition.

Incidence.—Carcinoma of the pancreas constitutes about 1.2% of all carcinomas. It usually occurs in middle or late life and is more commonly found in men than in women.

Pathology.—The tumor is an adenocarcinoma, usually scirrhous in type, which arises from the epithelium of the duct system. Occasionally it is medullary in type. The neoplasm develops in either the head or tail, or it may involve the entire gland. Carcinoma of the pancreas is most commonly found in the head, 81% of cases according to Berk. It may, of course, be found in the tail or invading the entire gland.

Carcinoma of the pancreas invades the adjacent structures early, and involvement of the vena cava and superior mesenteric and

portal veins frequently prevents pancreatic resection. Metastases occur in the liver and in the lymph nodes accompanying the pancreaticoduodenal, gastroduodenal, and celiac vessels. This problem of early invasion and metastatic spread is one that prevents successful surgical treatment, because when the patient begins to complain of sufficient pain and jaundice to warrant a diagnosis, the disease is far advanced.

Clinical Features.—The usual symptoms of carcinoma, namely, loss of weight, loss of strength, and loss of appetite, are present. Abdominal pain, usually epigastric, is frequent and is of boring character, generally radiating to the back. This pain is a common symptom and the old concept of painless jaundice being diagnostic of carcinoma of the pancreas no longer holds. Some degree of pain is present in over 80% of cases. Carcinoma of the tail or body of the pancreas does not produce jaundice unless it is very advanced. Pain comes on early and is typically the first sign. The tumor is rarely palpable. In patients without jaundice the presence of abdominal pain which radiates to the back, loss of weight, and loss of appetite are indications of pancreatic cancer.

Jaundice is present in 60-75% of all cases and is usually accompanied by pain of a dull, aching character which is frequently referred to the back. The patient also complains of a feeling of intra-abdominal pressure. The jaundice is of an obstructive type and is relatively severe. It is progressive and persistent in contradistinction to the jaundice that occurs as the result of carcinoma of the ampulla of Vater, which may be intermittent in character due to the ball valve action of a pedunculated tumor or necrosis of an obstructing tumor. There is occasionally occult blood in the stool, and blood and tumor cells may be found in aspirated duodenal contents. Ascites, when it occurs, is a late complication and is caused by portal vein obstruction due to lymph node involvement. The gall bladder is frequently palpable in carcinoma of the head of the pancreas. In addition to these signs and symptoms, there may be decreased sugar tolerance or diabetes, glycosuria, and diminution of external pancreatic secretion, as well as a slight elevation in the serum lipase.

Diagnosis.—The diagnosis is frequently difficult. It is made from the history, the presence of jaundice, and the employment of x-ray and other laboratory procedures. There may be an impaired carbohydrate metabolism. The typical x-ray finding in carcinoma of the head of the pancreas is a widening of the duodenal loop due to pressure when visualized by means of barium studies.

Treatment.—To date there has been no satisfactory form of treatment. Many techniques for resection of the involved portion of the gland with reconstitution of the gastrointestinal, biliary, and pancreatic flow have been devised. Such procedures are of value in that they relieve jaundice and thereby make the patient more comfortable. However, the operation is one with a significant mortality, and because of the fact that carcinoma of the pancreas infiltrates rapidly and metastasizes early, it is usually impossible to resect the entire area of malignancy. It is possible that a minute tumor could be cured by radical resection, but unfortunately by the time carcinoma of the pancreas is clinically obvious, it is no longer minute and is no longer amenable to curative surgery. Palliative treatment for severe jaundice with all its accompanying discomforts is helpful. This consists of drainage of the biliary system either externally or by biliary-intestinal anastomosis. The operation of choice is choledochointerostomy by the Roux-Y method. It is important that the gall bladder be removed, as its preservation affords a malfunctioning diverticulum of the biliary tree which is prone to infection and the development of lithiasis. The pain may be relieved by analgesics and by epidural alcohol block. It is not recommended that splanchicectomy be carried out for the relief of pain in these cases.

The duration of life is short once the diagnosis has been made (6-12 months).

Chapter 22

Surgery of the Spleen

Louis Lowenstein, MD. and Richard C. Long, MD.

INTRODUCTION

With few exceptions splenectomy is the only surgical procedure involved in diseases of the spleen.

It is stated that splenectomy was performed on Marathon contestants of the last century B C in order to increase their stamina. It is not improbable that a high percentage of individuals so treated were handicapped by massive malarial spleens and therefore benefited materially, in a purely mechanical sense, from the removal of such awkward abdominal tumors. In what manner and how frequently it was then possible to compass the technical hazards of operation remains to this day a matter for conjecture.

There are few authenticated records of splenectomy during the Middle Ages and Renaissance period. In 1856 Adelman of Berlin reported 15 cases but failed to mention the underlying pathologic conditions. In 1880 Pean is said to have removed the first splenic cyst. By 1900 Bessel-Hagen had operated upon 37 ruptured spleens. Since the turn of the century splenectomy has followed the general trend of technical improvement and has shared in the security of improved supportive treatment. It is performed with ever-increasing frequency and decreasing mortality. To the traditional indications for this operation—the rupture, ectopy and primary tumor—the expanding science of hematology has added vari-

ous blood dyscrasias. However, those of broadest experience will admit that removal of the spleen may be at times impossible and that the consequences of ill-advised surgical interference may be rapidly fatal.

Galen spoke prophetically when he described the spleen as an *organ full of mystery* and Stukeley's opinion (1723), that *what formerly was the seat of joy has become a topic of grief to the moderns*, is doubtless shared by many surgeons of our time.

APPLIED ANATOMY

The spleen is several times larger in life than in death. Its normal autopsy weight is about 100 grams. It is almost completely invested by peritoneum, of which various folds constitute suspensory ligaments; gastrosplenic, phrenicocolonic, lienorenal, and phrenicohepatic. The length of these peritoneal reflections determines the mobility of the spleen, which is subject to marked variation. The phrenicohepatic and phrenicocolic ligaments are normally folded of the lienorenal ligament contains no blood vessels. The gastrosplenic ligament contains the short gastric and left gastroepiploic branches of the splenic artery, and the lienorenal ligament enfolds the true splenic pedicle. In congestive splenomegaly, all the ligaments are highly vascular, and the spleen is often plastered to the diaphragm by tough adhesions rich in collateral vessels. The peritoneal relationships of the true pedicle make easier the

APPLIED ANATOMY

Fig 325—Peritoneal relations of the spleen

posterior approach to the vessels. From behind there is only one intervening layer of peritoneum, from the front, at least three, sometimes five

The spleen lies in the cupola of the left diaphragm. The 9th, 10th, and 11th ribs overlie its convex surface. Because of its situation, friability, and vascular turgidity, it is easily ruptured by direct or indirect violence. Anteromedially, the spleen is closely apposed to the stomach, posteromedially, to the left kidney, the tail of the pancreas, and the colon. Any of these structures is liable to injury during splenectomy.

Microscopic Features.—Besides its peritoneal covering, the spleen possesses a fibro-elastic coat from which trabeculae, penetrating in all directions, form the framework which supports the splenic pulp in its interspaces. The capsule and trabeculae of the human spleen are highly elastic but contain very little nonstriated muscle. Contractility is therefore passive rather than active, in contrast to what is found in laboratory animals. The pulp is a spongy, fibrocellular feltwork of reticulum, of which the meshes contain varying proportions of erythrocytes, lymphocytes, monocytes, reticulum cells, and granulocytes. Anas-

Fig 326—Ligation of splenic artery

The splenic artery lies above the splenic vein, behind the omental bursa, and parallel with the upper border of the pancreas. For purposes of ligation, it may be approached through either the gastrohepatic or the gastrosplenic omentum. Accessory spleens may be present. Their most common sites are the hilum of the spleen, the gastrosplenic omentum, the greater omentum, and the various peritoneal

ligaments. Each lymphoid cylinder surrounds a lobular branch of the splenic artery. The sharp demarcation of splenic infarcts confirms the frequency of vascular anastomoses. Though it has been described as a giant hemolymph node, the spleen contains no lymphatic vessels.

The microscopic vascular anatomy of the spleen remains a problem. The point of con-

troversty is whether or not the reticuloendothelial components of the pulp are directly exposed to the circulating blood; whether, in other words, the arterial and venous capillaries of the spleen consist of intact endothelial tubes in unbroken continuity, or whether a zone of naked pulp intervenes between them. The former type of circulation has been called *closed*, and the latter *open*. Direct observation of the microscopic circulation of certain mammalian spleens by a number of observers has led us to favor the hypothesis of a morpho-

logically open system which, from the standpoint of function, may be closed rhythmically or in response to those stimuli which cause arterial constriction

APPLIED PHYSIOLOGY

It is generally accepted that the spleen participates in the production, destruction, storage, and filtration of blood. While many of the details of these mechanisms are still obscure, many more have been clarified by recent investigation

Fig 327—Diagram of the intralobular circulation in certain mammalian spleens (e.g., that of the cat), as suggested, in part, by McNee's representation of a splenic lobule. Arrows radiating from ellipsoids and follicle capillaries suggest a few of the innumerable pathways by which blood may traverse the pulp interstices in relaxed or distended spleens and emphasize the morphologically "open" character of the circulation when the circulation is most of the blood, at artery; MF, Malpighian follicle, P, ellipsoid, R, red pulp reticulum, PS, pulp spaces, VS, venous sinus, ILV, intralobular vein, S, stigmas in walls of venous sinus and intralobular vein (From MacKenzie, D W, Jr, et al. Am J Anat 68: 397-456, 1941.)

Reservoir Function.—Since the classic experiments of Barcroft and his colleagues, it has been thought that the spleen serves as a reservoir of red cells which are released into the general circulation in response either to oxygen lack caused by violent exertion, hemorrhage, asphyxia, diminished atmospheric pressure, or carbon monoxide poisoning, or to any adrenergic stimulus that elicits contraction of the spleen. Anatomically, especially in those animals whose trabeculae contain an abundance of smooth muscle, the spleen is admirably adapted to mobilize its content of blood. In the normal human spleen there is doubt concerning the practical importance of this function, for it has been shown that, following exercise or injection of Adrenalin, hematocrit values increase in splenectomized individuals comparably to those with intact spleens and that in both there is an associated decrease in plasma volume. In certain diseases, however, usually associated with splenomegaly, enhancement of reservoir function may have an important bearing upon the pathologic physiology of the disease, as for example, in spherocytic anemia, hereditary or acquired sickle cell anemia, thalassemia major, and splenic hematopenia. The reservoir function of the spleen has been subdivided in a manner comparable to that of pulmonary function, namely, into complemental, tidal, reserve, and residual blood components.

Hematopoiesis.—Red cells are produced in the spleen during the first two trimesters of fetal life. Following birth, erythropoiesis in the spleen normally ceases. In certain diseases, with impaired hematopoiesis, usually as a result of replacement of normal marrow by abnormal tissue, erythropoiesis, granulocytopenia, and/or thrombocytopenia may again take place in the spleen, although this compensatory metaplasia is rarely sufficient to adequately replace the marrow hematopoiesis.

Remote Control of Hematopoiesis.—There is evidence that the normal spleen exerts a braking or inhibitory influence upon hematopoiesis in the bone marrow and also controls, to some extent, the maturation and possibly the delivery of red cells to the circulating blood.

To date, most of the evidence for this remote effect of the spleen has been based upon studies of bone marrow and blood before and after splenectomy. In normal persons, removal of the spleen is usually followed by leukocytosis, thrombocytosis, reticulocytosis, the appearance of nucleated red cells, Howell-Jolly bodies, and Cabot rings, basophilia, polychromatophilia, target cells, and increased resistance of erythrocytes to hypotonicity. Anemia may develop and is usually mild and transient. Howell-Jolly bodies have been observed in the red cells many years after splenectomy. The life span of transfused normal red cells is not affected by removal of the spleen. Leukocytosis may persist for years. At first, it is chiefly a neutrophilia. Subsequently the proportion of lymphocytes and monocytes increases. Eosinophilia and basophilia are occasional findings.

Recently, hyposplenism has been observed in nontropical sprue, in sickle cell anemia, and in certain cyanotic congenital heart lesions. In such cases, target cells and Howell-Jolly bodies were found, pointing an analogy to the effects of splenectomy in the normal individual and suggesting the possibility that functional *hyposplenism* as well as *hypersplenism* may occur.

Filtration of Blood.—The capacity of splenic sinusoids and pulp spaces to separate blood cells from blood fluid is readily observed in transilluminated spleens. The term *hematocrit function* aptly describes this activity. The reticuloendothelial components of the pulp, by adsorption and subsequent phagocytosis, immediately remove foreign particulate matter from the fluid which bathes them. This process, which is practically instantaneous, is strong evidence against the presence of a limiting membrane between the circulating blood and splenic pulp.

Blood Destruction.—There is abundant evidence that old or abnormal red cells are selectively trapped in, and destroyed by, the spleen. Though the function of iron storage has been attributed to the spleen, it is not clear that this mineral is retained in excess of the quantity derived from hemolyzed or phagocytosed erythrocytes. In certain diseases associated with excessive blood destruction, abnormal red cells are trapped in the spleen, filtered from the general circulation, and de-

stroyed by increased phagocytic activity. Leucocytes and blood platelets also are phagocytosed in some cases of hypersplenism.

Antibody Production.—Resistance to some infectious diseases is thought to be decreased after splenectomy. Recent evidence indicates that antibodies may be elaborated by and concentrated in the spleen; that, for example, the spleen is the major site of antibody production in some of the acquired hemolytic anemias, thrombocytopenic purpuras, splenic neutropenias, and hematomias. In this group of immunocytopenias the reservoir function, filtration mechanism, hematocrit, stagnating and phagocytic capacities of the spleen enhance the damaging effects of the antibodies. Although the evidence is still incomplete, it seems probable that the spleen is not the sole source of antibody production in the so-called immune types of cytopenias. However, in some instances it may be the major source.

In conclusion, the spleen is not essential to life, nor is its removal necessarily followed by any serious or permanent disturbance.

INDICATIONS FOR SPLENECTOMY

If more were known about the functions of the spleen, the indications for its removal could be stated with greater certainty. In cases of trauma, congenital ectopy, and mechanical exigency, the responsibility is purely surgical. Otherwise, the problem is to interpret the mechanism of imbalance between the hematopoietic functions of the bone marrow and the inhibitory and destructive activities of the spleen. Such interpretation, as has been amply demonstrated, demands the cooperative efforts of a team of hematologists, internists, and surgeons. Adequate preoperative investigation will eliminate most of the pitfalls and disasters of splenectomy. Prolonged follow-up, including frequent hematologic studies, will provide the only accurate assay of its results.

Generally speaking, the indications for splenectomy may be tabulated as follows:

Group I.—As a rule, the following conditions are absolute indications:

- 1 Rupture of the spleen
- 2 Torsion of splenic pedicle
- 3 Hereditary spherocytic anemia
- 4 Primary splenic hematoma

5. Primary malignant neoplasms of the spleen

6. Aneurysm of the splenic artery

Group II.—Splenectomy may be required for the following:

1. Idiopathic thrombocytopenic purpura
2. Acquired hemolytic anemia
3. Primary splenic hematoma
4. Cystic disease of the spleen
5. Abscess of the spleen
6. Granulomatous infections or parasitic infestations localized to the spleen
7. Hypersplenism secondary to a variety of causes
8. Gaucher's disease, myelofibrosis, kala-azar
9. Splenomegaly of indeterminable etiology
10. Congestive splenomegaly caused by obstruction of the splenic vein

Group III.—Splenectomy may expedite major surgical procedures involving:

1. Esophagus, stomach and pancreas, especially in block resections for malignant disease
2. Tributaries of the portal bed, in shunting operations for the relief of portal hypertension

CONTRAINDICATIONS OF SPLENECTOMY

Splenectomy is contraindicated in the following conditions:

1. Leukemia, lymphatic or myeloid, unless marked hypersplenism present
2. Polycythemia vera
3. Unless marked hypersplenism present, splenic metaplasia, associated with:
 - a. Secondary carcinoma of the bone marrow
 - b. Osteomyelofibrosis
 - c. Marrow bone disease
 - d. Refractory anemias resulting from various forms of intoxication (e.g., benzol or radium dial poisoning, or the effects of certain radioactive isotopes)

RUPTURE OF THE SPLEEN

Rupture of the spleen may be caused by direct or indirect violence or it may occur spontaneously. Its effects are either immediate or delayed. Diseased spleens, especially those of malaria, infectious mononucleosis, and acute

generalized infections, are far more liable to traumatic or spontaneous rupture than is the normal organ. It must be remembered, however, that the healthy spleen is more readily lacerated than any other abdominal viscus and that the injury may have been sufficiently trivial to be overlooked by the patient.

Clinical Features.—The signs and symptoms of ruptured spleen are those of internal hemorrhage together with peritoneal irritation. Shock may be immediate. There is abdominal pain, usually more marked in the left hypochondrium and flank. There is often reference of pain to the left shoulder. Muscular resistance is variably increased. Dullness to percussion may be present, shifting on the right but constant on the left side. The picture is frequently complicated by concomitant injury to other organs. In cases where the diagnosis is obscure, abdominal paracentesis with the finding of intraperitoneal blood should make one suspicious of a splenic rupture.

The initial phase may progress rapidly to a fatal termination. Fifty per cent of untreated patients die within an hour of injury. Bleeding may respond promptly to rest, sedation, and one or more blood transfusions, or it may continue slowly and persistently. Delayed hemorrhage is a dangerous complication of untreated rupture of the spleen. It occurs suddenly and without warning hours, days, or even months following the injury. It is due either to a subcapsular hematoma that breaks through the capsule or to a small tear in the spleen with hematoma formation and subsequent delayed hemorrhage.

Treatment.—If massive intra-abdominal hemorrhage is suspected, diagnostic abdominal paracentesis may be performed before laparotomy which must be undertaken as soon as maximum resuscitation has been achieved. Rupture of the spleen will be encountered in over 30% of all severe abdominal injuries. An upper left paramedian incision is preferred. The ruptured spleen, which is usually abnormally mobile, is delivered into the wound, and after its pedicle is secured and tied off, the organ is removed with the least possible delay. A search for other injuries is then carried out; the peritoneal cavity is cleansed and the abdomen closed. The operative mortality in cases

of ruptured spleen is at least 10%; of delayed rupture, 20%. Acute splenic rupture untreated causes death in over 75% of cases.

ECTOPIC SPLEEN

Ectopia of the spleen is a rare condition. It may be congenital, due to anomaly or absence of the supporting peritoneal ligaments, or acquired as a result of trauma which ruptures the phrenicocolic band, or because of splenic enlargement which stretches and abnormally mobilizes the peritoneal folds. A wandering spleen may be found in any part of the abdominal cavity, or it may be contained within a diaphragmatic or external hernial sac.

The important complication of this condition is twisting of the pedicle, which leads to hemorrhagic engorgement, necrosis, rupture, or atrophy. Such a spleen may be palpable and must be kept in mind in the presence of an intra-abdominal tumor.

Treatment.—Complicated or not, the wandering spleen should be removed.

HEREDITARY SPHEROCYTIC ANEMIA

Synonyms.—Chronic acholuric jaundice, congenital or familial hemolytic icterus.

Definition.—A form of hereditary hemolytic anemia transmitted as a simple mendelian dominant, characterized by jaundice, anemia, splenomegaly, spherocytosis, and increased fragility of red cells to hypotonicity. Hemoclastic crises, which are acute exacerbations of the hemolytic process, frequently occur.

Clinical Features.—Symptoms usually develop early in life. The blood of other members of the family may show traits of the disease. Anemia and icterus may be mild or severe; the patient is usually more yellow than sick. The onset may be initiated by an acute hemolytic crisis with pain in the back, abdomen, and limbs, severe malaise, chills, and fever, prostration, and occasionally circulatory collapse, oliguria, and even anuria. If the anemia is severe, dyspnea, palpitation, and other circulatory symptoms are prominent. Hemoglobinemia and hemoglobinuria are very rare. The urine may contain albumin and casts. Infection, trauma, fatigue, emotional crises,

exposure to cold, and occasionally pregnancy may precipitate an acute hemoclastic crisis.

The indirect plasma bilirubin is elevated, and urobilinogen excretion is increased in the stools and urine. The anemia is only severe during hemoclastic crises. Temporary hypoplasia or aplasia of bone marrow with rapid increase of anemia and decrease of reticulocyte, leukocyte, and platelet counts in the blood without significant increase of jaundice may occur early in an acute hemolytic crisis, especially if the crisis is precipitated by infection. There is a variable reticulocytosis, highest after severe hemolysis. The characteristic red cell is the *spherocyte*, a densely staining cell with decreased diameter and increased thickness as compared with normal erythrocytes. These spherocytes show increased fragility to hypotonic solutions and mechanical tests. The Coombs' antiglobulin test for coating antibodies is usually, but not invariably, negative (see Acquired Hemolytic Anemia). Although usually normal, white cells and platelets may be slightly decreased in number. The bone marrow shows normoblastic hyperplasia. Cholelithiasis occurs in approximately two thirds of cases. Radiologic changes in the bones may be found when anemia and jaundice are of long duration. The spleen is large and firm. Hepatomegaly is frequently observed, and the function of the liver may be impaired. Congenital abnormalities occur with unusual frequency.

Diagnosis.—The various causes of jaundice, fever, anemia, abdominal pain, splenomegaly, and cardiovascular disease must be considered. Cholelithiasis may obscure the primary diagnosis or may precipitate and be hidden by an acute hemolytic crisis.

Complications.—Cholelithiasis and acute hemolytic crises are the principal complications. Infrequently, anuria develops during a hemolytic crisis. Leg ulcers may occur and heal only after splenectomy.

Pathology.—The spleen usually weighs 800-1,500 grams but may be larger. Perisplenic adhesions are common. The cut surface of the spleen is purplish. Malpighian bodies are small and widely separated. Hemosiderosis occurs and, in supravital preparations, increased phagocytosis may be observed. The bone marrow shows a normoblastic hyperplasia.

Pathogenesis.—Most authorities now agree that the pathogenesis of this disease is a hereditary defect in carbohydrate metabolism of the red cells characterized by spherocytosis of adult erythrocytes. Such abnormal red cells are selectively destroyed by the spleen. The mechanism of destruction is unknown. A possible explanation is that the unique structure of the splenic pulp is particularly adapted to the mechanical trapping of spherocytic red cells, in the same manner in which it disposes of aging normal erythrocytes, which tend to become spheroidal.* This specific splenic hemolysis, in which the spleen apparently functions independently of the rest of the reticulo-endothelial system, occurs consistently only in the hereditary variety of spherocytic anemia. Red cells from patients with hereditary spherocytic anemia have a shorter than normal life span, both in their own circulation and when transfused into normal recipients. Their life span is increased both in splenectomized normal recipients and after splenectomy in patients with this disease. Normal red cells transfused into a patient with hereditary spherocytic anemia have a normal life span.

Treatment.—Splenectomy is almost invariably followed by the disappearance of anemia and jaundice. Preferably, splenectomy should precede biliary surgery. Contraction of the spleen prior to its removal may increase the red cell count by half a million or more per cubic millimeter. Leukocytosis occurs but is usually transient. A marked thrombocytosis probably accounts for the high incidence of postoperative thrombotic phenomena. If splenectomy does not achieve the desired result, resection of accessory spleens must be suspected. In some instances, subsequent removal of accessory spleens has resulted in permanent clinical cure. As a rule, spherocytosis and increased fragility are unaffected by splenectomy.

In this disease, preoperative transfusion of whole blood was formerly held to carry with it grave risk of serious reactions. It is our impression, however, that recent advances in

*Whipple and his co-workers have shown, in human subjects suffering from this disease, that the splenic artery contains many times more spherocytes than the splenic vein and that the splenic pulp spaces are packed with these abnormal erythrocytes.

Hematological Effects of Splenectomy

Fig. 128.—Hematologic effects of splenectomy in idiopathic thrombocytopenic purpura, hereditary spherocytic anemia, and splenic panhematopenia in congestive splenomegaly.

blood grouping and transfusion technique have reduced much of this hazard. Few patients with hereditary spherocytic anemia require pre-operative transfusions.

It has been stated that splenectomy is contraindicated during an acute hemoclastic crisis. Obviously, the operative risk is increased during an exacerbation of this disease, but so is the risk of expectant treatment. Current opinion generally supports the view that the results of surgical intervention are considerably better than those of nonsurgical supportive measures. There are occasional cases of congenital hemolytic anemia that are not spherocytic. These patients do not improve following splenectomy and they should be distinguished from those having the spherocytic variety.

IDIOPATHIC THROMBOCYTIC PURPURA (ITP)

Synonyms.—Thrombocytopenic purpura hemorrhagica, Werlhof's disease, thrombocytolytic purpura, hemogenic syndrome

Definition.—A condition of unknown etiology, most commonly occurring in children and in young adult females, characterized by thrombocytopenia and spontaneous bleeding. Spontaneous remissions and exacerbations are characteristic. At times there is a familial tendency. The disease is relatively uncommon in the Negro.

Clinical Features.—The onset may be explosive with gastrointestinal bleeding, cerebral hemorrhage, metrorrhagia, gross hematuria, or bleeding from the site of an extracted tooth. More often, however, it is insidious, with a history of easy bruising, of frequent epistaxis, or a tendency to bleed from the gums. The onset in children is frequently preceded by some acute infectious process. Spontaneous petechiae of the skin and mucous membranes usually occur before massive hemorrhage. Large ecchymotic areas may appear after trivial injuries. Hemarthrosis is rare.

The commonest physical signs are those resulting from hemorrhage. Blood absorption produces fever. The spleen is never markedly enlarged and is palpable in less than one third of cases.

The course of the disease may be fulminating and rapidly fatal, or it may develop in-

sidiously and exist for many years without severe manifestations. Spontaneous remission or recovery is common in childhood, uncommon after the age of 30 years.

Hematology.—Platelets are reduced and bleeding time is prolonged. Coagulation time is normal when determined by the usual methods, but the clot is friable and retracts poorly. However, a coagulation defect may be demonstrated by one of the prolonged clotting-time techniques, by the thromboplastin generation test, or by the prothrombin consumption test. The leukocytes show no consistent abnormality. The degree of thrombocytopenia varies greatly. Bleeding usually occurs if the platelet count is below 60,000. Clinical bleeding, however, does not necessarily parallel the platelet count, especially after splenectomy, and bleeding may be absent with a platelet count of less than 60,000. Prolongation of the bleeding time is usually proportional to the degree of thrombocytopenia. The tourniquet test shows an increased number of petechiae below a blood pressure cuff which has occluded the venous but not the arterial circulation, thus demonstrating the increased capillary fragility. After bleeding into the tissues has taken place, leukocytosis with a neutrophilia and a mild to moderate eosinophilia is not unusual.

The bone marrow findings are of great importance in excluding such conditions as leukemia, hypoplastic anemia, Gaucher's disease, or metastatic carcinoma, in which megakaryocytes are scanty. In ITP megakaryocytes are normal or increased in number. It has been contended that the megakaryocytes exhibit immaturity and impaired platelet proliferation, and that they return to normal, both morphologically and functionally, after splenectomy.

There is now abundant evidence that in many cases of ITP an immunologic mechanism is at work. The serum of a patient with ITP injected into a healthy subject produces a temporary depression of platelets. Some workers have succeeded in demonstrating platelet agglutinins *in vitro*, but the technique is difficult and uncertain and cannot be regarded as a routine laboratory procedure.

In some patients the Coombs' antiglobulin test has been positive, and occasionally there

is evidence also of an autoimmune hemolytic anemia. Thrombocytopenic purpura may be present for some time before an underlying disseminated lupus erythematosus becomes apparent and some apparent cases of ITP probably represent a phase in the course of lupus erythematosus.

Complications.—Bleeding is the chief complication. Its association with pregnancy deserves special mention, for 60 per cent of pregnant women with this disease do not survive. Mortality of the offspring is almost equally high. Over 15% of the children are themselves purpuric. Splenectomy may be performed in pregnancy with resultant survival of the mother.

Diagnosis.—Concealed hemorrhage may be difficult to diagnose. Bleeding into the kidney, the diaphragm, or the gastrointestinal tract may produce the symptoms of an acute surgical abdominal condition. Vaginal bleeding, due to purpura, must be differentiated from other causes. Intracranial hemorrhage may mimic a wide variety of neurologic lesions.

The differential diagnosis of the thrombotic diatheses must be considered. Thrombocytopenic purpura must be distinguished from purpura without thrombocytopenia and also from those conditions in which the thrombocytopenia is a secondary manifestation. A rare and fatal cause of thrombocytopenic purpura is the widespread formation of platelet thrombi in the capillaries and arterioles of females (thrombotic thrombocytopenic purpura). Various drugs such as Sedormid, quinidine, arsenamine, and the sulfonamides may produce thrombocytopenia. An antigen-antibody mechanism has been shown to cause the thrombocytopenia produced by Sedormid and quinidine. If the condition is associated with leukopenia or anemia, out of proportion to the amount of blood loss, aplastic or hypoplastic anemia must be considered. If there is a significant degree of anemia, lymphadenopathy, splenomegaly, or hepatomegaly, the possibility of leukemia should be entertained. Liver disease and congestive splenomegaly should be excluded. Carcinomatosis, Gaucher's disease, Hodgkin's disease, and lymphosarcoma involving the bone marrow may induce secondary thrombocytopenic purpura. Allergic thrombocytopenic purpura rarely occurs.

Treatment.—Blood transfusion has often proved lifesaving during the acute phase of the disease. Spontaneous remission may follow this phase, particularly in infancy and childhood. Transfusion is often essential in preoperative and postoperative management. Platelets disintegrate rapidly in ordinary preserved bank blood. If the early phases of coagulation are prevented by careful drawing of blood and by prompt mixing with the anticoagulant, platelets are preserved for a longer period. Fresh whole blood, platelet-rich plasma, and concentrated platelet suspension prepared by taking blood through plastic tubing into bottles coated with silicone or into plastic bags constitute the most effectual sources of platelets for transfusion in the order given.

ACTH and cortisone have resulted in clinical and hematologic remission for variable periods in this disease. In some instances remission has occurred and has been maintained after withdrawal of the steroid, in others the thrombocytopenia has relapsed after withdrawal, and in others steroid therapy has had no beneficial effect. ACTH and cortisone are often useful in presplenectomy and postsplenectomy management. Their beneficial effect is thought to be due to depression of antibody production and increase of platelet production.

During the first episode of thrombocytopenia, splenectomy should be undertaken only if medical management fails and if severe purpuric manifestations continue after intensive transfusion of platelet-rich blood or plasma. Medical management should be initiated with transfusion of platelet-rich blood or plasma and with the administration of 300 mg of cortisone daily in divided doses, or an equivalent amount of Meticorten. Intravenous ACTH may be used initially in the hope of obtaining more rapid action. Steroid therapy is usually required for a minimum of 2 weeks; as the platelets begin to rise the dosage may be gradually decreased. In mild attacks transfusion alone and careful observation may result in satisfactory remission.

In recurrent or chronic idiopathic thrombocytopenic purpura, splenectomy is indicated if medical management fails to produce improvement within a reasonable period of time. In an acute recurrence the waiting period should be at least 3-4 weeks, whereas in a patient

with mild symptoms the trial period of medical management may be prolonged for 4-6 months. Because idiopathic thrombocytopenic purpura in pregnancy results in a high maternal mortality, pregnancy is a definite indication for splenectomy in the presence of this disease. After splenectomy permanent remission develops in about two thirds of the patients; some of the remaining one third will show a temporary remission which may last weeks or months, and others will develop no remission. Accessory spleens are responsible for no more than one third of the failures. In some instances, clinical bleeding will decrease markedly or disappear after splenectomy, although the thrombocytopenia may persist.

SPLENIC HEMATOPENIA

Definition.—An acute, chronic, or recurrent disease syndrome characterized principally by splenomegaly, normal or overactive bone marrow, and varying degrees of anemia, neutropenia and thrombocytopenia.

The cause of these manifestations is said to be *hypersplenism*. It is thought that the spleen secretes a hormone which depresses maturation of normal cell components of the bone marrow and inhibits their delivery to the circulating blood and that, in addition, excessive destruction of the various cells occurs in the spleen. The syndrome, whatever its cause, is often cured by splenectomy.

Splenic hematopenia has been classified as primary or secondary. In the primary type, no cause is detectable. In the secondary variety, such conditions as Hodgkin's disease, Gaucher's disease, and cirrhosis of the liver with congestive splenomegaly may be etiologically significant.

Clinical Features.—These vary greatly and are largely dependent upon the relative degrees of anemia, neutropenia, and thrombocytopenia. The cellular components of the blood may be decreased singly or in any combination. For example, anemia and neutropenia with normal thrombocytes may occur in one case, in another, thrombocytopenia and neutropenia may be present without anemia. Most commonly, all three components are decreased.

The course of the disease may be acute with high fever, agranulocytic angina, stomati-

tis, oral ulcerations, and occasionally ulcers of the lower extremities. Anemia and purpura may dominate the picture. Lassitude, weakness, low grades of fever, and lowered resistance to infection are characteristic of chronic neutropenia. In some instances, neutropenia may recur in cycles. Occasionally, thrombocytopenia is associated with the menses. Anemia may or may not be hemolytic in character.

Hematologic Findings.—Blood and bone marrow findings are obviously dependent upon which cell type is predominantly involved. If there is a hemolytic reaction, reticulocytosis, increased fragility, spherocytosis of red cells, elevated indirect serum bilirubin, and increased secretion of urobilinogen in stools and urine are common. If there is no acceleration of red cell destruction or excessive bleeding, the anemia is usually normochromic and normocytic, without reticulocytosis or increased hemolysis. An essential diagnostic criterion is an active bone marrow with no abnormal cells.

Treatment.—Splenectomy is the treatment of choice. Blood transfusion may be required, and antibiotics are used to prevent and treat infection in the presence of neutropenia.

CHRONIC CONGESTIVE SPLENOMEGALY

The term splenic anemia was first introduced to describe anemia with splenomegaly not due to leukemia. In 1883 Banti recorded a syndrome of splenomegaly and anemia not associated with leukemia, Hodgkin's disease, malaria, syphilis, hemolytic icterus, or other recognizable pathologic conditions. He noted cirrhotic changes in the liver, a chronic sclerosing endophlebitis of the splenic vein, and typical changes in the spleen itself. It is now recognized that elevation of splenic vein pressure, due to whatever cause, may produce a symptom complex indistinguishable from that previously known as Banti's disease or syndrome and which is now most commonly referred to as *chronic congestive splenomegaly*. The majority believe that the etiology of this condition is obstruction in the portal circulation, which may be either intrahepatic or extrahepatic (see section on Portal Hypertension).

Clinical Features.—Splenic enlargement is usually marked. As noted by Banti, it is associated with anemia of moderate degree, which is normochromic and normocytic, unless complicated by hemorrhage or advanced hepatitis. A mild to marked leukopenia is more constant than anemia. Curiously, the relative percentages of all white cell types is unaffected by this numerical decrease. Thrombocytopenia is usually mild or moderate, but occasionally the platelets drop sufficiently to produce thrombocytopenic purpura. Bleeding from esophageal varices produces a posthemorrhagic anemia and masks typical hematologic findings. If severe liver disease is present, e.g., cirrhosis, a severe disturbance of blood coagulation may either contribute to or be solely responsible for gastrointestinal bleeding, thus the concentrations of prothrombin, proconvertin, proaccelerin, and fibrinogen may be decreased, antithrombin and/or fibrinolysin may be increased, and a variable thrombocytopenia may be present. In the presence of hepatitis the anemia becomes macrocytic. The disease usually appears before the age of 35, although it may develop either in infancy or old age.

PRIMARY NEOPLASMS OF THE SPLEEN

Neoplasms of the spleen are rare. Tumors may arise from the capsule and trabeculae, the lymphoid elements, endothelium, or various reticuloendothelial components. Primary carcinoma of the spleen is unknown. Metastatic carcinoma, especially from the lung and the breast, is present in about 2% of cases. Benign lesions, apart from their mechanical effects, are of little interest or importance. Twenty per cent of primary malignant tumors are lymphosarcomas.

Clinical Features.—The symptoms are those of a tumor in the left hypochondrium, inexpressible from the spleen, associated with anemia, cachexia, local pressure effects, and radiologic evidence of displacement of the stomach, colon, and occasionally kidney. There may be ascites and pleural effusion.

Treatment.—Because of the rapid growth and metastasis of such lesions, early splenectomy is the only hopeful treatment. At best, survival seldom exceeds 5 years.

ANEURYSM OF THE SPLENIC ARTERY

Aneurysm of the splenic artery is rarely encountered. Operation has been recorded in about 60 cases, of which 8% were correctly diagnosed before operation. The commonest causes are arteriosclerosis and embolism. Symptoms are usually vague and inconstant. There may be dyspepsia and epigastric pain. A pulsating tumor is rarely palpable. Warning hemorrhage may produce an upper abdominal crisis requiring emergency surgery. Otherwise, fatal rupture is almost invariable. Removal of the spleen together with the involved vessel is generally successful, if undertaken before rupture has occurred. After rupture, the operative mortality thus far approaches 80%.

CYSTIC DISEASE OF THE SPLEEN

Cysts of the spleen may be congenital or acquired. True cysts are dermoid, epidermoid, or endotheloid. False cysts are caused by trauma, infection, or parasitic (hydatid) infestation. They may develop following the degeneration of an infarcted area. The tumor may produce symptoms because of its large size, local pressure effects, or irritation of overlying peritoneum. X-rays aid in diagnosis by demonstrating displacement of adjacent organs. The treatment is splenectomy. Incision and drainage or marsupialization are reserved for complicated hydatid disease, when splenectomy is impossible. Enucleation of the cyst is no longer practiced.

ABSCESS OF THE SPLEEN

Abscess of the spleen is infrequent in temperate climates but may complicate the course of any acute specific infection such as typhoid fever, pyemia, bacterial endocarditis, and parasitic infestations (hydatid disease, malaria, and amebic dysentery). It sometimes follows trauma.

Clinical Features.—The signs and symptoms of splenic abscess are those of left subphrenic suppuration, but they may be delayed until a deeply placed focus has involved the peritoneal coat. Pain in the left upper abdomen, lower chest, and at times in the left supraclavicular

region is continuous, severe, and aggravated by respiratory excursions. Fever is high and associated with chills. The patient is acutely ill, suffers from diarrhea and vomiting, and rapidly loses weight. The abscess may penetrate into the general peritoneal cavity, into the subdiaphragmatic space, and thence into the pleura, into any adjacent abdominal viscus, or outward through the abdominal wall.

Treatment.—Splenectomy, in conjunction with appropriate chemotherapy, is the best form of treatment. In the presence of extensive suppuration, however, one must be content with incision and drainage.

GRANULOMATOUS INFECTIONS OF THE SPLEEN

Splenectomy has been performed for granulomatous infections, such as tuberculosis and syphilis, apparently localized to the spleen. In the light of modern medical therapy, such operations should be rarely, if ever, necessary.

Where endemic, malaria is the commonest cause of splenic enlargement, and removal of such spleens was formerly practiced in tropical zones. At present, medical therapy controls the situation in the vast majority of cases. Emergency surgery, however, is not infrequently required because of rupture or torsion of a large malarial spleen. The very large spleen frequently encountered in kala-azar may produce the clinical picture of hypersplenism, which is relieved by splenectomy.

Egyptian splenomegaly affords a classic example of Banti's syndrome produced by increased portal venous pressure. In this instance, the obstructive factor is intrahepatic, caused by the ova of *Schistosoma mansoni* and the cirrhotic changes they induce. Splenic enlargement is of the congestive type, and associated blood changes are those of hypersplenism. Though not curative, splenectomy may delay the advance of this disease which, untreated, progresses to liver atrophy, ascites, and death usually within 4 years of onset.

GAUCHER'S DISEASE

Definition.—A chronic, familial disorder characterized by splenomegaly, hepatomegaly, and skeletal defects caused by accumulations

of large pale cells (Gaucher's cells) containing the cerebroside kerosin.

Although familial, the disease rarely affects more than one generation and is most common among Jews. When the onset is within the first 6 months of life, death usually results before the end of the second year. Over half of the adult forms began in childhood.

Clinical Features.—Symptoms are chiefly related to bone involvement and to the mechanical disturbance caused by an enormous spleen. Invasion of the bone marrow by Gaucher's cells may cause such radiologic changes as decalcification, compensatory sclerosis, and pathologic fractures. Femora, vertebrae, and sternum are most frequently involved. The enlarged spleen may fill the abdomen. Being prone to infarction, it is frequently painful. The head, neck, and extremities often develop a brownish pigmentation. Wedge-shaped pingueculae and brownish pigmentation of the sclerae and conjunctivae may suggest the diagnosis.

Although the hematologic findings are to some extent those of secondary hypersplenism, their essential cause is the replacement of normal bone marrow by Gaucher's cells. Unless thrombocytopenia causes hemorrhage, the anemia is normochromic and normocytic. Occasionally, it may be macrocytic due to the presence of nucleated red cells and reticulocytes. Thrombocytopenic purpura develops in over half of the cases. Leukopenia and neutropenia are frequent and are usually associated with a relative lymphocytosis.

The diagnosis is established by marrow or splenic aspiration yielding the large, pale, kerosin-containing reticulum cells of Gaucher which, with Mallory's aniline blue stain, show numerous spiderlike fibrillae.

Treatment.—There is no curative treatment. However, such patients suffer from the effects of hypersplenism as well as from the encumbrance of a massive intra-abdominal tumor, and these symptoms may be alleviated by splenectomy.

ACQUIRED HEMOLYTIC ANEMIA

Definition.—Acquired hemolytic anemia may be idiopathic, or it may occur in association with a variety of granulomatous, pyogenic, or enteric infections, with Hodgkin's

disease, lymphosarcoma, reticulum cell sarcoma, leukemia, Gaucher's disease, schistosomiasis, ovarian cysts, and carcinomatosis.

Clinical Features.—If not idiopathic, the hemolytic anemia may be masked by the symptoms and signs of the primary disease. Its onset may be rapid and quickly fatal, or it may be a chronic affair, with prolonged anemia and jaundice, recurring remissions, and exacerbations. In contrast to hereditary hemolytic icterus, the patient is often more sick than jaundiced. Anemia and jaundice, with elevation of the indirect plasma bilirubin and increased output of fecal and urinary urobilinogen, are present in varying degrees, depending on the rate of hemolysis. These classic signs of hemolytic anemia may be lacking in the presence of fairly brisk hemolysis. Red cell survival measured with radiochromium-tagged red cells will sometimes show the presence of hemolysis when the usual signs are absent. The red cells exhibit increased fragility to hypotonicity and in about one half of the cases may have, in addition, lowered resistance to mechanical agitation. The anemia is usually normocytic but may be macrocytic. Spherocytosis is present in some cases. Reticulocytosis, polychromatophilia, basophilia, and basophilic stippling reflect increased erythropoiesis. Autoagglutinins, pathologic cold agglutinins, and atypical agglutinins, most commonly warm, and incomplete antibodies are often demonstrable. The Coombs' test for coating antibodies is usually positive in idiopathic acquired hemolytic anemia. It is almost always negative in hereditary spherocytic anemia and, consequently, is useful in differentiating the two types. The test usually remains positive after splenectomy. The life span of normal red cells is shortened when they are transfused into a patient with this condition, and red cells from a patient with acquired hemolytic anemia survive normally when transfused into a normal person. These findings confirm the presence of a hemolytic factor in the plasma of patients with acquired hemolytic anemia and exclude the presence of an inherent defect of the red cell.

Treatment.—Treatment of idiopathic acquired hemolytic anemia is usually medical at the outset. Blood transfusions and steroid

hormone therapy are the mainstays. Whether or not the spleen should be removed is a difficult decision, and the criteria for selection of cases are not at present well defined. The results are uncertain. About 50% of splenectomized patients may be expected to respond fairly well to the operation. However, relapse may occur sooner or later. The ultimate decision is usually based on failure of medical treatment. Recently selection of cases for splenectomy has been helped by determining the localization of transfused red cells in the spleen when these cells were tagged with radioactive chromium.

Multiple blood transfusions, so frequently required in these patients, may lead to the development of new isoimmune antibodies and the occurrence of transfusion reactions. Because of this, the blood transfusion laboratory should employ the technique of high protein and indirect Coombs' cross-matching. The use of packed red cells or saline-washed red cells may be necessary to avoid transfusion reactions.

If there is an underlying disease causing the hemolytic anemia, this should be treated in the appropriate way. Occasionally, lymphocytic leukemia or lymphosarcoma may present a severe hemolytic anemia with a huge spleen which makes management difficult because of the requirement for frequent blood transfusions. Splenectomy may be very helpful in such patients.

SPLENOMEGALY OF INDETERMINABLE ETIOLOGY

Enlargement of the spleen, sufficient to be palpated beneath the costal margin, is noted on occasions without demonstrable cause. Blood and bone marrow changes are absent. There is no general or localized lymphadenopathy. Portal venous pressure is normal. Signs of bacterial infection or parasitic infestation are lacking. There is no gross metabolic disturbance.

In such cases, the presence of some obscure pathologic process, localized to the spleen, cannot be excluded. For this reason, it is the opinion of some surgeons that splenectomy for splenomegaly alone deserves serious consideration.

SUPPLEMENTARY SPLENECTOMY

Removal of the normal spleen may greatly facilitate major surgical procedures on the upper abdomen and thorax and at the same time render these operations more effectual, particularly when their purpose is the eradication of malignant disease. Block resection of the spleen, the greater and gastrohepatic omenta, together with the stomach, increases the scope of radical operation for gastric cancer. Esophagoduodenal anastomosis is performed much more easily and safely in the absence of the spleen. The same applies to abdominal repairs of large diaphragmatic hernias, with or without incarceration of the spleen.

TECHNIQUE OF SPLENECTOMY

When the spleen is sufficiently mobile to be lifted out of the abdominal incision, its removal is a technically simple and safe procedure. When it is bound down by dense, vascular adhesions, splenectomy may have to be abandoned and the operation consist of some palliative procedure such as ligation of the splenic artery or division of as much of the vascular pedicle as can be safely reached.

Preoperative Measures—Facilities for blood transfusion should be available. The stomach is intubated and kept deflated throughout the procedure to permit better exposure. Optimum posture is obtained with an air cushion supporting the lower left ribs and flank and the table tilted slightly to the right.

Operative Incision.—Most surgeons prefer a long, left paramedian, epigastric incision. However, in some hands the curved, subcostal approach has been highly satisfactory, especially when the spleen is greatly enlarged and the subcostal angle markedly widened. In cases of suspected rupture, a midline epigastric incision may be advisable. It can be opened and closed more swiftly than the others and affords easier access to the right upper quadrant. The abdomino-thoracic approach, combining a transverse or left paramedian epigastric incision with an extension through the bed of the 8th rib or 8th intercostal space and the diaphragm, has been recommended for difficult splenectomies. Thoracotomy, however, increases the operative risk.

Removal of the Spleen.—As soon as the abdomen has been opened, thorough exploration must be carried out. Injury to other organs must be excluded in accident cases, complicating regional extensions in inflammatory disease, metastases in neoplasms, and calculous biliary disease in spherocytic jaundice. In this last condition and in thrombocytopenic purpura, accessory spleens must be removed. In congestive states, the site of portal obstruction should be accurately determined.

When the spleen is intact, free from adhesions, and not too large, the following procedure is recommended. The lower two thirds of the gastrosplenic ligament is divided between clamps. The spleen is tilted medially, the costal margin retracted, and the lienorenal ligament, together with its underlying areolar tissue, incised. The stomach and spleen are drawn downward and to the right to fully expose the very short upper third of the gastrosplenic ligament, which is then safely clamped and divided. When the avascular phrenicocolic band is cut, the spleen is fully mobilized and may be lifted into the incision. The tail of the pancreas is carefully dissected away from the lower posterior portion of the pedicle. The splenic artery is divided between heavy ligatures. After a brief interval, to permit collapse of the spleen, the veins are individually ligated and divided and the specimen is removed. If the splenic reservoir is large, its evacuation may be hastened by the injection of a few minims of adrenalin into the artery just before it is tied. The pedicle stump is peritonealized and the roof of the lesser sac is reconstructed with a few interrupted sutures. The abdominal incision is closed in layers. Drainage is indicated in the presence of persistent bleeding, injury to the pancreas or established infection.

Perisplenic adhesions may be delicate and relatively bloodless, or dense and vascular. The former yield, as a rule safely, to manual exploration, but the latter have called a halt to many splenectomies. To cope with this type, the use of high-frequency current has been recommended.

As a prelude to difficult splenectomies, it is sound policy to ligate the splenic artery. The vessel may be approached via the gastrohepatic omentum and tied close to its origin, or

Fig 329—Technique of splenectomy

through the gastrocolic omentum and secured where it parallels the superior border of the pancreas, several centimeters from the pedicle. Such a step will lessen blood loss and permit the patient to transfuse himself with the reservoir content of his spleen. Some feel that splenic artery ligation per se affords considerable palliation in cases of advanced cirrhosis that will not tolerate major vascular shunts. This we doubt (see Portal Hypertension).

Complications of Splenectomy

The complications of splenectomy may be the result of errors in technique, errors in judgment, and other causes relevant to certain types of splenopathy.

Technical errors may lead to postoperative hemorrhage, damage to adjacent viscera with subsequent perforation, peritonitis, and fistula formation, infection consequent to local contamination and inadequate hemostasis, and wound disruption because of infection or faulty suture technique. The operation may be useless because of failure to remove accessory spleens. Expert hematologic advice is the only safeguard against errors in the selection of cases for splenectomy.

In certain splenopathies, various postoperative complications are more commonly recorded. The removal of large spleens predisposes to pulmonary collapse and pneumonia. Temporary paralysis of the diaphragm occurs frequently. While it is often stated that there is an increased incidence of postoperative thrombosis following splenectomy, it is our feeling that this risk has been overrated. This is true in spite of the thrombocytosis which occurs. Debilitated individuals with congested, adherent spleens are particularly liable to develop left subdiaphragmatic suppuration. Hemorrhagic diatheses and malnutrition delay wound healing and pave the way for disruption. Closure therefore must be especially meticulous. Nonabsorbable suture material is preferable to catgut.

Chapter 23

Peritoneum, Omenta, and Mesenteries

James R. McCorrison, M.D.

INTRODUCTION

The peritoneum is the lining of the abdominal cavity. It is a serous membrane, derived from the mesenchyme, with a surface area approximately that of the skin. Since the peritoneum is in intimate contact with the intra-abdominal organs, the retroperitoneal tissues, the diaphragm, and the abdominal parietes, it is not surprising that it is involved in a wide variety of disease processes, the majority of which have their origin in other tissues and organs.

EMBRYOLOGY

In the embryo, after the somatopleure and the splanchnopleure develop, the mesoderm splits laterally into the dorsal somatic mesoderm and the ventral splanchnic mesoderm. The cavity thus formed is the body cavity or celom which eventually is divided into the pericardial, pleural, and peritoneal cavities. Variations may occur in the development of the peritoneum and mesenteries, but these are so numerous that no attempt will be made to describe each one separately. It is sufficient to realize that variations can and do occur with surprising frequency. Certain variations may be present throughout life without causing symptoms, whereas others may lead to serious conditions such as internal hernia, volvulus, or intestinal obstruction.

ANATOMY

In the male the peritoneum forms a closed sac, but in the female the free ends of the fallopian tubes open into the peritoneal cavity. The mesothelial cells which form the peritoneal surface are flattened and polygonal, separated by cement substance. This layer of cells rests on a thin layer of fibrous tissue which is connected to underlying fascia or viscera by areolar tissue.

The continuous peritoneal membrane is invaginated by the hollow and solid viscera. This portion constitutes the visceral peritoneum, while the remainder is called the parietal peritoneum. The mesenteries of the bowel are formed by the two layers of invaginated peritoneum, and the greater omentum is an extensive fold hanging from the greater curvature of the stomach. The peritoneal cavity is between the parietal and visceral peritoneum and contains, normally, only a small amount of serous fluid which lubricates its lining. The heavy folds of peritoneum attached to solid organs constitute their ligaments. The blood vessels, nerves, and lymphatic vessels are important additional supports, especially in the mesenteries of the bowels.

Anatomically, the peritoneal cavity is divided into two major compartments, the greater and lesser sacs, which communicate by means of the epiploic foramen (foramen of Winslow).

Fig 330--The peritoneum (median sagittal section) This drawing illustrates diagrammatically the relationships of the omenta, transverse mesocolon, and mesentery of the small intestine

Fig 331--The subphrenic spaces The six subphrenic spaces are shown from the anterior aspect. The right lobe of the liver is drawn medially and rotated upward

FUNCTIONS AND REACTIONS

From a surgical point of view, there are four main divisions: (1) supracolic, (2) right infracolic, (3) left infracolic, and (4) pelvic.

Surgically, the supracolic subdivision may be looked upon as the *subphrenic space*, as it lies between the diaphragm above and the transverse colon and its mesocolon below. This region is divided by the liver into suprahepatic and infrahepatic portions. Three suprahepatic and three infrahepatic spaces exist. The falciform ligament divides the suprahepatic space into right and left parts. On the right side the right triangular ligament of the liver separates a large anterior space from a small posterior space. The left triangular ligament extends along the posterior border of the left lobe of the liver, separating the superior from the inferior surface. Therefore only one space exists to the left of the falciform ligament.

The three suprahepatic spaces are named: (1) right superior anterior subphrenic space, (2) right superior posterior subphrenic space, and (3) left superior subphrenic space.

The infrahepatic region is divided into right and left parts by the second (descending) part of the duodenum. To the right of the duodenum and below the liver is the space often called Morison's pouch. To the left of the duodenum the space is divided into anterior and posterior parts by the stomach and lesser omentum.

The three infrahepatic spaces are named: (1) right inferior anterior subphrenic space (Morison's pouch), (2) left inferior anterior subphrenic space, and (3) left inferior posterior subphrenic space (lesser sac).

These six spaces are all intraperitoneal, but an extraperitoneal space exists which corresponds to the bare area of the liver.

The right infracolic is separated from the left infracolic subdivision of the peritoneal cavity by the mesentery of the small bowel. The right and left paracolic gutters are important because they provide routes for the ascent and descent of exudate or pus. The pelvic subdivision is within the confines of the true bony pelvis.

glide freely over each other and parietal peritoneum. The peritoneum marked capacity to absorb both small particles. Fluids that are not with body fluids are usually rendered before absorption takes place; then of absorption may be rapid. The capillary portal system are extremely permeable to protein molecules. Absorption of electrolytes and of crystalloids by capillaries is rapid and complete. Macrophages, blood cells and particulate matter, the absorptive power of the greater omentum is enhanced by its mobility.

Under conditions of stress the peritoneal cells are probably capable of giving rise to macrophage cells. In any event the peritoneum has, at times, enormous powers of resistance to infection, which is exemplified by the fact that pure cultures of pathogenic bacteria introduced into the peritoneal cavity usually produce peritonitis, unless there is some traumatization or the introduction of some material. It has been shown that the capacity of absorption and resistance are approximately equal in all parts of the peritoneum. It is probable that the peritoneum reacts against infection in the presence of an infective process. Although, grossly, there may be localization of infection, diffuse or generalized peritonitis is one area of the peritoneum in which the whole peritoneum pours forth exudate in a defensive effort.

The sensitivity of the peritoneum to pain is clinically important. The peritoneum has few or no nerves, but the bowel wall is supplied by the parasympathetic nervous system (of the vagus nerve), while the parietal peritoneum is supplied by fibers of the sympathetic system. The wall of the intestine is not burned, crushed, or cut without pain, but traction or tension on many parts of the peritoneum is painful. The parietal peritoneum reacts to trauma as do other parts of the body supplied by cerebrospinal nerve fibers. The peritoneum which do

forms in the wound it is covered with mesothelium, and scarring is minimal. In the presence of severe trauma or infection, repair is by second intention; scar tissue is greater in amount and adhesions or bands, which are often dangerous, may form. Such adhesions are primarily beneficial since they splint the parts, prevent or control leakage of exudate, and permit complete healing. Once the acute phase is past, these adhesions tend to stretch, ultimately lose their blood supply, and are absorbed. Adhesions which develop as a consequence of inflammatory processes have frequently disappeared by the time of a later abdominal operation. Although adhesions are necessary for repair, if there is much tissue trauma or extensive peritonitis they may become dense, are not absorbed, and may lead to intestinal obstruction or lesser degrees of interference with function.

Mechanical and chemical injuries to the peritoneum are the commonest types. The injury may also initiate the reaction known as inflammation. If there is a peritoneal wound or tissue death, the process of repair will also be initiated.

The peritoneal fluid is normally small in amount, clear, and viscid. It contains cells, over 90% of which are large mononuclear, polymorphonuclear, and basophilic cells.

When an irritant is placed in the peritoneal cavity, polymorphonuclear leukocytes flood the region and become the predominant cells. Within a few hours mononuclear macrophages appear in large numbers in the increasing volume of peritoneal fluid which also contains fibrin. Foreign particles or bacteria are caught in the meshes of clotted fibrin, and phagocytosis occurs. As the days pass, the cells degenerate and, together with their phagocytosed contents, disappear. After several days, when the process subsides, the peritoneal fluid returns to normal. The preceding description is that of mild peritonitis which results in resolution, but all grades of severity of the reaction can occur, and if the infection is very intense, death may result from toxic absorption, dehydration, electrolyte imbalance, and other secondary factors. The inflammatory response of the peritoneum is shared by the underlying and surrounding tissues.

When the peritoneum is divided or devitalized, repair follows. The process of inflammation is set up, and fibrinous tissue fluid causes adhesions to form, which are at first fibrinous but which may later become fibrous. The degree of development of adhesions depends upon many factors, not the least of which is the inherent tendency of certain individuals to form adhesions. The factors that influence the formation and disappearance of adhesions are not understood, so that various methods for their prevention have rarely proved successful. Gentle operative technique, removal of blood and foreign materials, and reduction of bacterial contamination to a minimum are the best means of avoiding persistent adhesions.

ACUTE PERITONITIS

Peritonitis is the term that denotes any inflammatory process in the peritoneum, regardless of its extent or severity. Peritonitis may be *bacterial* or *chemical*, and it varies in extent from localized to generalized. Non-bacterial peritonitis follows the introduction of sterile traumatizing or irritating substances into the peritoneal cavity. Body fluids such as bile or gastric juice, clotted blood, gauze, sulfonamide crystals, surgical instruments, talcum powder, and antiseptics all produce peritonitis with signs and symptoms indistinguishable from those of bacterial infection. More severe grades of peritonitis are caused by bacteria which are usually of intestinal origin. Pyogenic peritonitis is generally caused by one or a combination of two or more of the following bacteria: coliform bacteria, staphylococci, streptococci. Other organisms are frequently found, particularly anaerobes (e.g., gas-forming pathogens). Many of these organisms produce powerful toxins which seem to be responsible for the severe toxemia often found and which are more important as a cause of death than bacteremia.

SECONDARY PERITONITIS

Acute bacterial peritonitis follows direct contamination when bacteria reach the peritoneum secondarily from an intra-abdominal viscus, some adjacent tissue or organ, or through an abdominal wound.

Locally, in bacterial peritonitis, the peritoneum soon becomes reddened and edematous, loses its normal sheen, and is covered with fibrinopurulent exudate and later pus. Such an exudate, bathing the bowel wall, causes decrease or loss of peristalsis, leading to distention. The greater omentum may be successful in limiting the process to a localized peritonitis (or abscess), but if localization does not result, diffuse or generalized peritonitis ensues. When a relatively large focus of peritonitis is suddenly set up, absorption of toxic materials occurs over an extensive surface. The route of spread depends upon local anatomic structures such as the paracolic gutters, gravitational spread into the pelvis, or the watershed effect of the mesentery of the small bowel.

It has been pointed out that the surface area of the peritoneum is approximately that of the skin, and widespread peritonitis is, therefore, comparable to a very extensive cutaneous burn. Many general effects result from severe widespread peritonitis:

1. Edema of the inflamed tissues pools body fluid which is initially at the expense of the extracellular fluid and later depletes the intracellular fluid. This is actually the creation of a third fluid space in addition to the intracellular and extracellular spaces. As a result there are hemoconcentration, hypoproteinemia, hypochloremia, and reduction of circulating blood volume. This, in turn, produces a degree of stagnant anoxemia.

2. Bacteremia, toxemia, and hemoconcentration all destroy erythrocytes, producing anemia.

3. Peritoneal exudate and edema of the bowel wall inhibit peristalsis and so cause paralytic ileus. The concomitant distention exerts upward pressure on the diaphragm and secondarily interferes with pulmonary function.

4. When obstruction of the bowel is caused by paralytic ileus, vomiting occurs, accelerating the process of dehydration.

5. Dehydration and associated factors interfere with renal function, resulting in azotemia and oliguria or anuria.

All of these effects vary in degree of severity according to the suddenness of the inflammation and the treatment provided.

Diagnosis.—In the diagnosis of peritonitis, its presence, and then its source, must be determined. Initially, the symptoms and signs of peritonitis may not be distinguishable from those of the intra-abdominal lesion causing it. The fever is usually high, particularly so in children. Only in overwhelming infections is shock present and the temperature subnormal. The white blood cell count is high (e.g., 20,000-30,000/c.mm.) with over 80% polymorphonuclear leukocytes present. The patient is distressed and concerned about his illness. He adopts a position in bed which reduces intra-abdominal tension to a minimum, i.e., his knees and hips are flexed and he breathes rapidly and shallowly. He tends to lie quite still, for any movement causes an increase in discomfort owing to stretching or moving of the inflamed peritoneum and mesenteries. Examination of the abdomen will show some degree of distention, increased tone of abdominal muscles, and local or generalized tenderness with or without rebound pain. In the presence of acute peritonitis, especially when it is localized, the tenderness is usually pronounced. Tenderness, elicited by means of rectal or vaginal examination, is acute in cases of pelvic and generalized peritonitis. In the later stages of severe peritonitis marked abdominal distention, vomiting, oliguria, coated tongue, foul breath, spiking fever, restlessness with picking at the bed coverings, delirium, and finally coma occur. X-ray films of the abdomen will reveal dilated loops of bowel with fluid levels.

Conditions which may be confused with peritonitis, particularly early acute peritonitis, include pneumonia, pleurisy, influenza, renal colic, retroperitoneal hemorrhage, and retroperitoneal tumors. Once the presence of peritonitis is diagnosed, there follows the task of determining its source. Sources of peritonitis are discussed elsewhere under the various intra-abdominal lesions.

Treatment.—The treatment of peritonitis includes the following:

1. Prevention by means of prompt attention to its cause.
2. Elimination of the focus of infection.
3. Prevention and treatment of complications.

4. Inhibition or destruction of the bacteria with chemotherapeutic and antibiotic agents when possible

5. Provision of early drainage of abscesses
Although it is at times advisable to postpone operative treatment until the general condition of a very ill patient is improved, removal or drainage of the focus of infection is very important. Closure of a perforated peptic ulcer and removal of an inflamed appendix are examples of procedures used in this connection which should be carried out with minimal delay

Complications of peritonitis may be both numerous and dangerous and may lead to the death of the patient besides prolonging the disease. Toxemia, ileus, pneumonia, actual organic bowel obstruction, and septicemia are examples of grave complications of peritonitis.

Chemotherapeutic agents are employed to great advantage in the prevention and treatment of peritonitis, and their use does not interfere with other methods of treatment. When peritonitis is caused by an organism or organisms sensitive to these agents, they become indispensable. Vaccines are of no practical value.

In all cases of peritonitis close attention must be paid to the maintenance of fluid and electrolyte balance and the provision of blood transfusions when indicated. The intestines are kept at rest by means of continuous nasogastric or intestinal tube suction; morphine is used to allay fear, anxiety, and pain, and nothing is permitted by mouth. Morphine diminishes peristalsis of the gut and simultaneously increases the tone of its muscle. Patency of the suction tube may be assured by irrigating it every 2 or 4 hours with 30 ml of physiologic saline solution, although this is not always necessary. Because production and absorption of vitamins in the alimentary tract are seriously interfered with in peritonitis, and because ordinary parenteral fluids contain no vitamins, parenteral vitamins in high dosage must be given daily.

PRIMARY PERITONITIS

Primary peritonitis is rare and may be looked upon as metastatic peritonitis, since the bacteria reach the peritoneum indirectly from an outside focus of infection. It may begin after

pathogenic organisms reach the peritoneum via the fallopian tubes or via the lymphatics, but the common route is the blood stream. Organisms can usually be found in the blood in these cases, and often a respiratory infection is present beforehand. The lesions are typical of generalized peritonitis, the type of exudate present depending upon the causative organism. Primary peritonitis is usually caused by the streptococcus or pneumococcus. A less common causative organism is Friedländer's bacillus.

Pneumococcal Peritonitis.—Pneumococci reach the peritoneum via the blood stream from a focus in the respiratory tract, the accessory nasal sinuses, or the middle ear, or from the genital tract of female infants or children through the fallopian tubes. The pneumococcus causes acute peritonitis, and a thick, whitish exudate is formed. Cultures of peritoneal exudate yield pure pneumococcus. Characteristically the fever is quite high and may rise to 104° F. The leukocyte count is usually very high, often in the neighborhood of 25,000-30,000/c mm.

Streptococcal Peritonitis.—This form of metastatic peritonitis leads to the production of a serosanguineous exudate which, on culture, yields pure streptococcus.

Acute primary peritonitis produces signs and symptoms of generalized peritonitis without localization. Foci of infection leading to primary peritonitis are hard to differentiate and may coexist. For this reason surgical exploration is not infrequently indicated as soon as the patient's general condition permits. When the peritoneal cavity is opened, a culture and direct smear of the exudate should be made. If pure streptococcus or pneumococcus is found on examination of the smear, the abdominal wound should be closed without further traumatizing exploration. Treatment thereafter is conservative, consisting of general supportive and symptomatic measures combined with chemotherapy guided by sensitivity tests performed on the cultured causative organism.

LOCALIZED ABSCESSES

Acute bacterial peritonitis tends either to resolve completely or to localize and form one

or more abscesses. An abscess, in turn, may undergo resolution and may point toward the surface of the body and discharge its contents or toward an abdominal viscus (e.g., rectum). At times such an abscess may become dormant for long periods of time, later resolving or flaring up to produce further tissue destruction. Not infrequently diffuse or generalized peritonitis becomes loculated so that multiple abscesses develop.

Abscesses develop in certain sites which warrant separate consideration since the conditions leading to them and their treatment differ.

Subphrenic Abscess.—In the section on Anatomy, the subphrenic spaces were considered in detail because of their importance in respect to abscesses which may develop within them. Subphrenic abscess is often difficult to diagnose because of the paucity of local

Fig 332.—Subphrenic abscess in right superior anterior space. This is a single x ray film of the abdomen, with the patient erect, after the introduction of 1,500 ml of oxygen into the peritoneal cavity. The right half of the diaphragm is elevated, inferior to it can be seen the shadows of inflammatory pneumoperitoneum to a lower level.

physical signs, although general signs and symptoms of severe infection may be present, with spiking fever, severe malaise, high leukocyte count, and secondary anemia. When the superior subphrenic spaces and the bare area of the liver are sites of abscess formation, signs and symptoms of pleural and pulmonary involvement are usually present, whereas, if the inferior subphrenic spaces are involved, abdominal signs and symptoms predominate. A right superior anterior subphrenic space abscess, for example, often leads to pleural irritation, with the development of a pleural exudate and secondary lower lobe atelectasis. The abscess may penetrate the diaphragm and pleura, producing empyema and lung abscess. A most important diagnostic aid in detecting or confirming the presence of a superior subphrenic space abscess is the use of fluoroscopy and x-ray films, with or without induced pneumoperitoneum. Owing to the presence of the subphrenic abscess, the involved hemidiaphragm is elevated and relatively motionless on respiration, and the abscess may throw a soft-tissue shadow or displace the liver downward. When gas-forming organisms are present in the abscess, a fluid level will be seen with an overlying bubble of gas. When gas cannot be seen on x-ray examination, the failure of oxygen in an induced pneumoperitoneum to enter the superior subphrenic space is evidence of abnormal adherence of the serosa of the liver to the parietal peritoneum over the diaphragm. When doubt as to the diagnosis and site of a subphrenic abscess exists, it is at times helpful to attempt aspiration of pus by means of a syringe and wide-bore needle. Great care must be taken to avoid contamination of the pleural space or perforation of bowel during this maneuver.

Inferior subphrenic abscesses, if large, may be detected as abdominal masses, and x-ray examination (particularly with the aid of barium) may demonstrate displacement of the stomach or duodenum from its normal position.

Although the subphrenic spaces may become infected by organisms carried by the blood stream, the usual means of infection is the introduction of infected material from an

abdominal viscus (e.g., perforated peptic ulcer, gall bladder, or appendix; bowel surgery; suppurative pancreatitis).

Pelvic Abscess.—Any type of bacterial pelvic peritonitis may lead to the formation of a pelvic abscess, although it may also result from the gravitational spread of infected material from any site in the abdomen. Pelvic abscess develops most commonly following pelvic inflammatory disease in the female, suppurative appendicitis, and infective lesions of the large bowel. In addition to the general signs and symptoms of infection, there are definite local signs and symptoms which permit the diagnosis to be made with certainty. Owing to irritation of the pelvic colon and rectum there is usually diarrhea, often accompanied by the passage of mucus in large amounts. Rectal examination will reveal the presence of a boggy, tender mass pressing against the rectum. If it is large, abdominal examination may reveal a tender mass rising out of the pelvis. Often a pelvic mass causes irritation of the bladder, with symptoms of dysuria and frequency. In the female, pelvic examination will add to the information gained by rectal examination.

Paracolic Abscesses.—Abscesses develop frequently enough in the paracolic gutters and in the iliac fossae to warrant separate mention. On the right side, lesions of the appendix and right colon and, on the left, lesions of the pelvic colon are the common starting points of paracolic abscesses.

Treatment of Localized Abscesses.—In addition to conservative supportive measures and chemotherapy, localized abscesses require operative drainage in most instances. The indications for operative drainage include progression of the abscess, spread, pressure effects (e.g., pressure on the common bile duct by a right inferior subphrenic abscess), septicemia, intestinal obstruction, and failure to respond to conservative measures. In certain instances concomitant operative treatment of a causative lesion (e.g., previously undiagnosed perforated peptic ulcer) is necessary.

The surgical approach for drainage of right superior anterior subphrenic abscess is via a right subcostal incision with care to avoid opening the uninvolved peritoneal cavity. The

right superior posterior subphrenic space may be drained by means of an extrapleural approach, through the bed of the 11th or 12th rib. The left superior and inferior anterior subphrenic spaces may be drained through a left subcostal incision. The right inferior subphrenic space may be approached through a high right paramedian abdominal or subcostal incision, taking advantage, when possible, of previous postoperative adhesions to avoid contaminating the remainder of the peritoneal cavity. The left inferior posterior space (lesser sac) may be drained transperitoneally or retroperitoneally by means of an incision through the bed of the left 12th rib.

A pelvic abscess can usually be drained through the rectum or vagina, although it may be necessary to employ an abdominal route.

Right and left paracolic abscesses may be drained by means of incisions directly over them, with care to avoid opening the uninvolved peritoneal cavity.

The contents of abscesses should always be cultured and chemotherapy guided by the type of organism present and its sensitivity to particular antibiotic agents. At times it is of great value to irrigate an abscess cavity at intervals with a suitable antibiotic in solution. When it is not feasible to provide dependent drainage, it is desirable to posture the patient to attain this end.

SPECIAL FORMS OF PERITONITIS

Tuberculous Peritonitis

Tuberculous peritonitis is more frequent in females than in males and in the young than in the aged. Frequently it is one manifestation of miliary disease but may take origin from an abdominal organ. It often originates in the fallopian tubes and in the appendix. There are two chief forms of tuberculous peritonitis.

1. The *exudative type* is a slowly developing disease which leads to the formation of ascites and small, gray tubercles studding the peritoneum.

2. The *proliferative or dry type* often goes on to the formation of areas of caseation and fistulous connections between loops of bowel. External fistulas are likely to follow surgical procedures. Much granulation tissue develops, forming matted masses in the abdomen, par-

ticularly in the pelvis. If tuberculous peritonitis is not associated with widespread tuberculosis elsewhere, the prognosis is fairly good.

Diagnosis.—In tuberculous peritonitis the abdomen is distended but not markedly tender on palpation. Frequently the abdomen has a doughlike consistency, and a mass can be palpated owing to the rolling up of the greater omentum which often occurs. The onset is usually gradual or it may be abrupt, with signs and symptoms very similar to those of acute pyogenic peritonitis (see above). There are usually low-grade fever, general malaise, loss of weight, and some abdominal discomfort with a feeling of fullness. The presence of tuberculosis elsewhere in the body is a common finding. The white blood cell count tends to be normal or only slightly elevated, with a relative lymphocytosis and monocytosis.

Treatment.—The basis of treatment is general supportive measures and rest as for tuberculosis elsewhere. Streptomycin, para-aminosalicylic acid and isoniazid compounds have been used with success. Foci of infection, such as the appendix or fallopian tube, should be removed surgically. Strangely enough, simple laparotomy often benefits the patient.

Gonococcal Peritonitis

Gonococcal peritonitis arises secondary to infection of the female genitalia. It is rarely fatal but is important because of the necessity to differentiate it from diffuse peritonitis of other origin. When the diagnosis is not clear, it is safer to explore the right lower quadrant and remove the appendix than to risk delay should the lesion prove to be acute appendicitis.

Treatment.—The treatment of acute gonococcal peritonitis is general supportive measures, bed rest, and penicillin in high dosage. Operative treatment is used only to drain persistent abscesses or to remove a chronic tubo-ovarian abscess (See also Chapter 28, The Female Genital Tract.)

Miscellaneous Types

In acute rheumatic fever the peritoneum may become inflamed. Actinomyces may cause peritonitis, as may brucellae and lymphogranuloma venereum.

CHRONIC PERITONITIS

It must be remembered that any type of acute peritonitis may become chronic, with thickening of the peritoneum and the formation of widespread, dense adhesions. When peritonitis lasts more than a few days, peritoneal reaction cells appear, which are probably phagocytic and which resemble large mononuclear cells. Sections of such peritoneum show that these cells project from the surface. Quantities of cloudy peritoneal fluid often persist in chronic peritonitis, which, on culture, prove to be sterile. Such collections are often found in the vicinity of walled-off intraperitoneal abscesses.

Granulomas

In addition to chronic infective granulomas, such as tuberculosis and actinomycosis, the peritoneum may be involved in granulomatous processes caused by irritating foreign material.

Talc Granuloma.—Talcum powder as a surgical glove and instrument powder is now being replaced by other substances but is still in fairly widespread use. Talc crystals in contact with the peritoneum act as an irritant, causing a foreign body reaction. Ordinarily this reaction subsides after a time and no harmful effects are noted clinically. However, in certain individuals, talc in the peritoneal cavity leads to a very pronounced reaction which is proliferative, producing widespread adhesions and masses of granulation tissue which resemble a slowly growing neoplasm. Harmful effects may appear when such masses become bulky and widespread adhesions interfere with bowel function.

Prophylaxis is secured by using other types of surgical glove powder or by careful washing of the gloves and instruments before introducing them into the peritoneal cavity during an operation. Treatment of the established granuloma consists of relieving complications, such as intestinal obstruction due to adhesions, by appropriate surgical procedures. On a few occasions it has been possible to excise granulomatous masses.

Sulfonamide Crystal Granuloma.—Sulfonamide crystals, placed in the peritoneal cavity for the prevention and treatment of infection, occasionally cause a granulomatous reaction

with widespread vicious adhesion formation. Crystalline sulfathiazole has been the worst offender because of its low solubility.

Granulomas Due to Nonabsorbable Suture Material.—A small foreign body granuloma forms about every nonabsorbable suture placed in the peritoneum as in other tissues. These reactions seldom reach harmful proportions unless secondary bacterial infection supervenes. If infection persists, sinuses often develop and persist until the suture material is discharged or removed surgically.

TUMORS AND CYSTS

Primary tumors of the peritoneum, omenta, and mesenteries are extremely rare. There is only one true primary tumor of the peritoneum, the so-called *mesothelioma* (*endothelioma*) which is diffusely infiltrating and malignant.

Cysts of the omenta and mesenteries are rare. *Lymphatic cysts* of the mesentery are considered to be congenital lymphangiomas. They are often single and vary from a few centimeters in diameter to a very large size. They have milky contents and a flat endothelial lining. *Gas cysts* are very rare, occurring in clusters along the mesentery of the small bowel. Such a cyst may rupture spontaneously, leading to pneumoperitoneum and abdominal pain. The diagnosis of pneumoperitoneum can be made roentgenographically, but laparotomy may be necessary to exclude perforation of a hollow viscus. *Hydatid cysts* of the mesentery form multiple masses, sometimes of large size.

Metastatic malignant tumors (usually carcinomas) frequently involve the peritoneum. The three most common intra-abdominal primary sites are the stomach, large bowel, and ovary. Spread is direct by penetration of the serosa and dissemination over the serous surface. Implantations may appear in isolated places at a distance from the parent tumor. When metastasis is widespread throughout the peritoneal cavity, it is called abdominal carcinomatosis. Irritation of the peritoneum causes ascites to develop and the fluid is often sanguineous. Metastasis from primary neoplasms at distant sites may occur in the peritoneum, carried by lymphatics, or, more commonly, in the blood stream (e.g., malignant melanoma).

Tumors arising in the retroperitoneal tissues, whether benign or malignant, are similar to tumors of connective tissue origin elsewhere. Retroperitoneal lipoma and sarcoma are the most common types.

It is noteworthy that peritoneal tumors are often very difficult to diagnose by the usual means of examination, including x-ray methods. If there is free peritoneal fluid present, it should be aspirated and studied carefully, with attention to the type of cells present, bacterial culture, guinea pig inoculation for tubercle bacilli, direct smear, specific gravity, protein content, and microscopic appearance of sections of the sediment.

Treatment.—There is no curative treatment for primary mesothelioma of the peritoneum. Paracentesis abdominis may be performed at intervals if a large volume of peritoneal fluid collects.

Cysts of the omenta and mesenteries require no treatment unless they become very large and cause symptoms. Benign cysts may be carefully dissected out of the mesentery or, if in the greater omentum, may be removed along with surrounding omentum.

Treatment of metastatic peritoneal tumors is limited to palliative operations to relieve symptoms and interference with bowel function except in cases of carcinomatosis peritonei with ascites, where the introduction of radioactive gold seems to be beneficial by reducing the ascites in certain instances. X-ray therapy is of questionable value except, perhaps, in the case of certain radiosensitive sarcomas.

Pseudomyxoma Peritonei

This curious condition may follow rupture of a pseudomucinous cyst of the ovary or of a mucocele of the appendix. Sometimes the entire peritoneal surface is studded with small tumor nodules which secrete an enormous amount of jellylike material that accumulates in the peritoneal cavity. This material acts as an irritant, producing a low-grade peritonitis with the formation of adhesions. The signs and symptoms include abdominal distention, pain, and interference with bowel function.

The treatment is removal of the primary focus, which occasionally results in the disappearance of the whole lesion, but the prog-

nosis is usually poor. In a limited number of cases x-ray therapy has apparently caused arrest or regression of the lesion. Radioactive gold may prove to be useful. This condition must be differentiated microscopically from metastatic colloid carcinoma.

THE APPENDICES EPILOICAE

Significant lesions of the appendices epiploicae rarely occur, but torsion of an appendix epiploica may produce the clinical picture of an acute abdominal emergency. Occasionally the blood supply of an appendix epiploica is interfered with and it undergoes calcification, appearing then as a calcified shadow in x-ray films.

ASCITES

Ascites is an accumulation of serous fluid in the peritoneal cavity. The fluid may be a transudate or an exudate.

An *exudate* is a collection of fluid secondary to an inflammatory process and may be clear, turbid, or purulent, depending on the number of cells present. Blood may be present. The specific gravity is over 1.018 and the protein content over 30 Gm/L.

A *transudate* is a noninflammatory collection of fluid. Such fluid is clear, of light straw color, with a specific gravity below 1.018 and usually below 1.015. The cell count is low and the protein content under 30 Gm/L.

There are many causes of ascites. General causes include cardiac failure, renal disease, constrictive pericarditis, and increased mediastinal venous pressure. Depletion of the plasma protein results in a decrease in plasma osmotic pressure and ascites. Locally, an increase in portal vein pressure from hepatic disease or obstruction of the portal system, an increase in lymphatic pressure from neoplastic or inflammatory obstruction of lymphatic vessels, or rarely an ovarian neoplasm (Meig's syndrome) can cause ascites.

Treatment of ascites may be divided into two broad categories: (1) conservative and (2) operative treatment.

Conservative treatment is of prime importance and is directed toward raising the serum albumin concentration, restriction of salt intake, use of mercurial diuretic agents, and cor-

such as pinworms, seeds, and indigestible food are an unusual and almost accidental cause of appendicitis. Anaerobic microorganisms may also play a part in the development of gangrene.

There is no evidence that the state of health of the patient plays a part in the etiology, as many healthy youngsters come to operation with all degrees of appendicitis and recover immediately when the offending organ is removed, unless complications delay the progress.

Recurrent attacks of appendicitis result in fibrosis with a narrowing of the lumen, and this may give rise to symptoms of partial obstruction. At times the obstruction may be complete, leading to obliterative appendicitis and occasionally to empyema of the appendix, or mucocele.

Bacteriology and Pathology

The commonest organism cultured in cases of appendicitis is the colon bacillus. However, infections are mostly mixed and the streptococcus plays an important role. In fact it may be the primary cause. The improvement obtained in many cases by penicillin would appear to support this view. In gangrenous appendicitis one of the anaerobic organisms, such as Welch's bacillus, may be a factor, as suggested by occasional postoperative infection in the abdominal wall.

Pathologically, the changes in appendicitis range from simple catarrhal inflammation to gangrene. A small area may show edema, round-celled infiltration, ulceration of the mucosa, suppurative inflammation, or necrosis. On the other hand, the whole appendix may be involved in an acute inflammatory process, and be red, edematous, friable, and gangrenous. An abscess may occur in the wall, or in the periappendicular tissue. A spreading peritonitis may be present with turbid fluid, or the infection may spread to the entire abdomen, causing general peritonitis. The cecum may be involved and become infected, edematous, and friable, a point to be remembered when one considers inverting the base of the appendix in such cases. In an effort to wall off the infection, the omentum may wrap itself around the appendix and form a mass readily palpable on examination but indistinguishable

from a localized abscess. The small bowel may become adherent and give rise to symptoms of partial obstruction.

Clinical Picture

In considering the clinical picture of appendicitis, it will be easier to classify it into acute, subacute, and chronic forms. The acute form should be divided into two fundamentally different types, the first of which is acute inflammation of the wall, and the second, acute obstruction of the lumen, or closed loop obstruction, which was originally described by the late Professor Wilkie of Edinburgh.

ACUTE APPENDICITIS

Acute Inflammation of the Wall (Acute Appendicitis).—Although diagnosis is very simple in a typical case of appendicitis, few diseases present so many diagnostic variants. The typical picture is one in which recent abdominal discomfort centers around the umbilicus and is accompanied by nausea and frequently vomiting. Later the pain becomes localized in the right lower quadrant, with rebound tenderness, increased resistance and tenderness in the right iliac fossa, and tenderness on rectal examination, especially on the right side. The temperature is usually 99°-100° F., with a leukocytosis of 10,000-14,000. If examination of the chest and the urine is negative, the diagnosis is established. The history is frequently of short duration, although there may have been previous attacks.

Diagnostic difficulties increase if the appendix is retrocecal, if it lies along the lateral wall of the cecum, hangs over the brim of the pelvis, or lies adjacent to the ureter. Difficulties are further increased by the type of pathologic change—catarrhal, acute fulminating, perforating, abscess forming, gangrenous or obstructive.

In children, the picture of appendicitis is considerably different from that of the adult. In apparently healthy children, crying and vague tenderness in the right iliac fossa may be the only signs of an acute appendicitis, so that extreme care in examination is necessary. On the other hand, this is the age of exanthemas, many of which have transitory

Plate 28.—The Pathologic Appendix.

abdominal pain. Gastroenteritis is also common during this period, and the best differential method is to administer sweetened fruit juices which act as a mild intestinal sedative in gastroenteritis but do not affect the pain of appendicitis. Fever may be unusually high, or the temperature may be normal. The leukocyte count is not of much help as it may be extremely high—20,000 or as low as 3,000–4,000.

Acute appendicitis occurring during pregnancy is most common around the 3rd month. It presents no special difficulty at this time. Later, as the uterus enlarges, the position of the appendix is higher and the problems increase until just before and immediately after term, when diagnosis is much more difficult. Fortunately it is a rare occurrence at this stage. If strict attention is paid to the usual signs, the diagnosis can be made. Removal must be carried out immediately. Gentleness and care will preclude interference with the pregnancy. Antibiotics will control the infective process. Cesarean section, if contemplated, should not be performed until approximately one month later. The diagnosis of appendicitis during the puerperium is the most difficult of all, and it requires extremely careful study before it can be established. The treatment is appendectomy.

In the aged, appendicitis is less common because of the gradual obliterative process that takes place during the years, but this may predispose to a closed loop obstruction and be all the more serious in elderly patients with low resistance. Here, the only safeguard is to remember appendicitis as a possible diagnosis.

The original pain in the epigastrium or around the umbilicus is usually of a cramplike nature, but when it settles in the right lower quadrant, it is steady and is increased by movement or blowing out of the abdominal wall. Sudden release of pressure on the right side of the abdomen causes pain in the right iliac fossa, so-called rebound pain. This test should not be carried out too vigorously as it could conceivably break down recently formed adhesions and spread the infection. Rovsing's sign is frequently present—pressure over the large bowel causes pain in the right

iliac fossa. Hyperesthesia is often found over the appendix. If the lumen of the appendix is obstructed, the pain is usually crampy, or colicky in nature, and in the early stages muscular resistance is unusual. When the appendix is in the retrocecal position all signs are less marked, because it is shielded by the cecum. When the appendix lies in the lateral paracolic gutter, the pain and tenderness may be localized in the flank. If it is adjacent to the ureter, a few red blood cells may be found in the urine on microscopic examination.

Though the point of maximum tenderness is usually in the neighborhood of McBurney's point, this depends on the site of the appendix. The degree of tenderness and muscular spasm also depends on the position of the appendix, being much more marked when the organ lies against the parietal peritoneum of the right iliac fossa. Tenderness on rectal examination is more marked if the appendix is situated in the pelvis. If a mass is felt, it is due either to the presence of an abscess or to the omentum walling off the appendix as a protective mechanism. The temperature will increase as the infection spreads, with a rise in the pulse rate. When the patient is seen early in an attack, it is unwise to delay treatment because of the absence of fever or tachycardia.

Psoas spasm is a common sign, especially in retrocecal appendicitis. This is elicited by hyperextending the thigh or by flexing and adducting it against resistance. Obturator spasm may be present, especially when the appendix lies in the pelvis, and can be noted by flexing the thigh and internally rotating the leg, which gives pain through spasm of the internal obturator muscle. While a history of constipation is frequently elicited, diarrhea may occur in appendicitis. As a rule, however, this suggests enteritis, and great care should be taken to establish the diagnosis before surgical intervention is undertaken.

Acute Obstruction of the Lumen (Closed Loop Obstruction).—The main characteristic of the obstructive type is an intermittent, crampy pain which is very severe and made worse by movement. The cessation of this crampy pain is indicative of perforation, relieving the tension of the closed loop obstruction, but pain will recur in a few hours as a

generalized peritonitis develops. In the early case of appendicular colic, which, as Wilkie states, so often goes on to perforation, it is usual to find a normal pulse and leukocyte count, but both of these will rise as soon as inflammatory changes develop, either in the wall or surrounding tissue. When leukocytosis is present, the differential count shows a marked increase in the polymorphonuclear cells, with a shift to the left or to the more primitive forms.

Differential Diagnosis

A surgeon should consider the patient with an acute abdomen from two points of view: first, what is the most serious diagnosis, and, second, are the signs and symptoms of such a nature that a laparotomy is advisable in spite of a failure to make a definite diagnosis. The latter observation applies especially to young children and to the aged. Many of the patients in these groups are left until perforation occurs because, until then, the signs are indefinite. In children, early pneumonia may simulate appendicitis, but the tenderness and spasm are less marked, the pain is frequently higher, and the respiratory rate is increased and is frequently accompanied by movement of the abdominal wall and alae nasae. The fever, pulse rate, and leukocyte count are higher than in appendicitis.

In considering the differential diagnosis, it seems easier to classify the conditions into three groups:

1. Those associated with pain and protective muscular resistance
2. Those with pain but without muscular resistance
3. Those associated with a mass in the right iliac fossa

With Pain and Protective Muscular Resistance

Acute Salpingitis.—In the female, acute salpingitis frequently presents diagnostic difficulties. The most important diagnostic points are the history of exposure, a burning sensation on urination, a vaginal discharge, obtaining a drop of pus by milking the urethra, and marked tenderness on moving the cervix.

The sedimentation rate usually shows a greater increase than in appendicitis. If the tenderness is bilateral on bimanual pelvic examination, a waiting policy with the use of antibiotics is advisable.

Ruptured Ectopic Gestation.—Internal hemorrhage and shock predominate, with softening of the cervix and moderate enlargement of the uterus. There is usually a history of a missed period.

Early Pneumonia.—Early pneumonia, especially of the basal type, not only in children but sometimes in adults, may cause confusion. An x-ray of the chest and careful examination of the site of the pain localization is necessary. In pneumonia it is usually higher in the abdomen and is associated with an increased respiratory rate.

Perforated Peptic Ulcer.—A perforated peptic ulcer usually gives a characteristic board-like rigidity in the upper half of the abdomen, but if the gastric contents move down the right paracolic gutter, pain, tenderness, and even a mass may be found in the right iliac fossa. A history suggestive of a chronic ulcer may offer a clue. A plain film of the abdomen showing free gas under the diaphragm, along with an accurate history, should assure a correct diagnosis.

Acute Cholecystitis.—Acute gall bladder conditions may also simulate acute appendicitis. The appendix in cases of non-descent of the cecum may be adjacent to the gall bladder or the liver, and the gall bladder may lie lower than usual. It is important to know whether the patient has had previous attacks of pain in the right hypochondrium. Radiation of pain to the angle of the scapula or to the back, or a history of stultent indigestion, especially in a middle-aged obese female, suggests gall bladder disease. Further, in cases of acute cholecystitis, the globular tender surface of the gall bladder, moving with respiration, can usually be palpated, and a positive Murphy's sign is pathognomonic.

Regional Ileitis.—This may be confused with recurrent appendicitis. The long history of cramps and diarrhea with gastrointestinal disturbances suggests the advisability of having a barium series, with follow through of the barium through the ileum, when the character-

istic picture of "string and puddle" confirms the diagnosis. In the acute stage of this condition it may be impossible to differentiate the condition prior to operation.

Mesenteric Lymphadenitis.—The initial centralized abdominal pain and muscle spasm of acute appendicitis are absent, but otherwise the picture is remarkably similar. Most cases are diagnosed correctly only when the abdomen has been opened.

Genitourinary Conditions.—Hydronephrosis and pyelitis frequently mimic acute appendicitis, especially during pregnancy. The presence of blood or pus in the urine, the radiation of pain from the loin to the inguinal region, or genitalia, the palpation of a tender kidney, and the demonstration of a renal or ureteric calculus by a skiagram are important. In pyelitis a catheterized specimen of urine will show gross pus, the fever is higher, and prostration may be present. Tenderness is usually situated in the loin.

Pneumococcal Peritonitis.—This occurs in young girls in the lower socioeconomic group between the ages 5-8 years. It is usually primary but occasionally may be secondary to pneumonia or otitis media. When primary, the infection is thought to ascend by way of the patent fallopian tubes. The symptoms are high fever, with diarrhea and vomiting. On palpation, a doughy, slightly distended abdomen is felt in a thin young individual. The treatment is operative. This confirms the diagnosis and permits the local administration of penicillin.

Pain Without Muscular Resistance

Colic, whether biliary or renal, is usually due to a stone passing down the duct and is frequently severe. The patient moves about in agony but is comfortable between attacks.

Biliary Colic.—The pain radiates to the back and shoulders, and there is usually a history of previous attacks. There is flatulence, indigestion, and occasionally jaundice.

Renal Colic.—There is frequency of micturition and the pain usually radiates from the loin to the genitalia. Urinary investigation revealing blood and pus cells in the urine and the roentgenologic demonstration of a calculus are important.

Appendicular Colic.—Appendicular colic is usually of an entirely different character from the other colics. It is better described as a sudden cramplike abdominal pain of varying intensity, with no relation to meals, and frequently accompanied by nausea, vomiting, and headache. Examination is negative, unless the obstruction continues into obstructive appendicitis.

Mass in Right Iliac Fossa

The presence of a mass in the right lower abdomen may be due to one of the following:

Appendicular Abscess.—This is one of the presenting signs of appendicitis.

Ovarian Cyst.—Small follicular cysts are very common and only cause pain when they rupture. They are frequently too small to be felt on examination. On the other hand, larger ovarian cysts, about the size of a fetal head, can be felt on pelvic examination. They tend to become twisted and thus cause pain which is aggravated by movement.

There are several other chronic conditions which may cause a mass or pain in the right lower abdomen, but the distinguishing features should be brought out by the history, examination, and special investigations.

It should be stressed that acute appendicitis is the commonest surgical abdominal condition and that most of the other conditions which have been mentioned are relatively uncommon. The most important differentiation is that of early pneumonia, when unnecessary operation is hazardous and must be avoided.

Complications

Abscess.—This is the commonest complication of appendicitis and, of necessity, means that the infection has spread through the wall or that the appendix has perforated and the infection has been localized by means of the omentum wrapping itself around the infected organ. The position of the abscess will depend on the position of the appendix. The four situations have already been referred to but will be mentioned again.

Retrocecal. This is associated with psoas spasm and is usually late in appearing. It may point in the groin.

Pelvic. When the appendix is in the pelvic position, the infection spreads down into the pelvis and frequently causes irritation to the bladder and rectum, with frequency of micturition and diarrhea. On rectal examination there is a tender, boggy mass in the pelvis, which may be fluctuant.

Intestinal. When the appendix lies between the coils of the small intestine, the abscess is localized in between these coils and presents as an enteritis. A mass may be present, which, however, may be very difficult to feel because it is masked by the distended intestine.

Juxtaparietal. The appendix lying next to the parietal peritoneum causes early irritation and is therefore usually dealt with before abscess formation takes place. However, the

Paralytic Ileus.—With peritonitis alone, the patient recovers, but should paralytic ileus develop, the prognosis is grave. It is due to severe toxic infection which paralyzes the small bowel and causes increasing distention.

Thrombosis of the Portal Vein.—This is due to the infection spreading into the venous system. When this spreads to the liver, suppurative pyelphlebitis develops, with chills and high fever, and an enlarged, tender liver. Fortunately, with the use of the antibiotic and earlier operative interference, this complication is now rarely encountered.

Pulmonary Embolism.—This may occur after any operation, from thrombi originating in the veins of the legs and pelvis. Small make themselves evident by pain in the

Fig. 336.—Sites of localized peritonitis depending upon position of appendix

localizing adhesions or the omentum may form a mass in the peritoneal cavity near the anterior abdominal wall.

Subphrenic abscess is becoming less common after appendicitis and is usually a residuum of generalized peritonitis.

Generalized, Spreading Peritonitis.—Generalized, spreading peritonitis with failure to localize the perforated or infected appendix is a serious complication. There is widespread abdominal tenderness, increased pulse rate, and boardlike rigidity of the abdominal wall. This is soon followed by the hippocratic faces and abdominal distention.

and the spitting of blood. A large embolus usually occurs suddenly without warning about the 10th day and is commonly fatal.

Treatment

The treatment of acute appendicitis is the removal of the organ as soon as the diagnosis is made. To delay only means to court complications. Perforation may occur within a few hours and may be precipitated by the administration of cathartics. Only when operative removal is impossible is it permissible to temporize. The patient is placed in Fowler's position, nothing is given by mouth, and anti-

iotics are administered. Cold compresses should be applied to the abdomen to slow down the process and relieve the pain.

Operation

For the sake of clarity, the operative treatment will be divided into that for the unruptured and ruptured appendix.

Removal of the appendix is carried out under aseptic conditions; spinal or general anesthetic may be used.

The skin incision may be oblique, or transverse following Langer's lines, with the center of the incision at McBurney's point. The subcutaneous fascia is next incised. The external oblique aponeurosis is opened in the direction of the fibers. The internal oblique and transversalis muscles are separated in the direction of their fibers, and by gentle traction, the peritoneum is exposed. This is carefully lifted and opened, and the cecum usually presents. If the finger is curled around the taenia, the cecum can usually be delivered through the wound. Where the three taeniae converge, the base of the appendix will be found. The appendix is then carefully delivered through the wound, and the mesoappendix, containing the appendicular artery, is clamped, divided, and ligated. A purse-string suture is placed about the base of the appendix, and the surrounding area is covered with moist gauze. The base of the appendix is then clamped with forceps and the crushed portion tied near the base. The appendix is then severed with the actual cautery, and the stump of the appendix is invaginated by means of the purse string which is tied. The raw area of the mesoappendix is carefully covered. The small bowel should be examined for a distance of 3 feet to rule out the presence of a Meckel's diverticulum and enlarged lymphatic nodes in the mesentery of the small bowel. In females, the uterus and appendages are palpated with the two fingers. The wound is closed in layers with interrupted sutures, without drainage.

In some cases this gridiron incision is not adequate, but when necessary it may be extended medially to the sheath of the rectus muscle. When the appendix is adherent and cannot be delivered, it may be advisable to cut the base and dissect the appendix out in

a retrograde fashion. When the diagnosis is in doubt, a lower paramedian incision rather than a gridiron should be used.

The choice of the incision is governed by the type of patient and the certainty of the diagnosis. The McBurney or gridiron incision just described may, if necessary, be extended medially to the rectus muscle. This is in effect a transverse incision, and in adults may be used to explore the peritoneal cavity. In children, it may be further extended into a complete transverse one. The disadvantage of a long transverse incision at this level in the presence of infection is the danger of an incisional hernia which is extremely difficult to repair. The better choice therefore for exploration of the whole of the peritoneal cavity, particularly in females, or for a laparotomy in males, is the paramedian incision centered slightly below and to the right of the umbilicus.

When a localized abscess is encountered and the appendix presents easily, the organ is removed as described above and the abscess is drained through the incision or a separate stab wound. If, however, an abscess is encountered and the appendix is not readily available, then it is wise merely to drain it and leave the appendix to be removed at a later date, usually 3 months afterward. The danger of breaking down a natural barrier and spreading the infection is more serious than leaving the organ where the infection has already spread beyond its limits. If the cecum is edematous and friable, it may be impossible to invert the stump of the appendix, and in such cases the omentum may be gently sutured over the cecum as a further precaution.

Ruptured Appendix.—The perforated gangrenous appendix with a generalized peritonitis is a serious condition. The appendix is therefore removed as quickly and as gently as possible, and second, the peritoneal cavity should be drained. Usually the drains are placed in the most dependent position or where the infection is most likely to localize, such as the pelvis, retrocecal fossa, or toward the ileocecal mesentery.

In localized abscesses, and, in fact, even in generalized peritonitis, topical application of penicillin and streptomycin into the cavity

Fig 337—Stages of appendectomy

through a small catheter beside the drain has been of great value. The local concentration is about one thousand times higher than with parenteral administration, and the formation of adhesions has been minimal. This should be continued for 2-3 days, using 500,000 units of penicillin and 0.5 Gm of streptomycin. Other antibiotics such as Aureomycin, Chloromycetin, Terramycin, or neomycin may be added as desired.

Expectant Treatment

The expectant treatment advised by Ochsner and Sherrin is really the treatment of a localized abscess or inflammatory mass of some duration. It should never be used in the treatment of acute appendicitis except in cases occurring in isolated areas where adequate surgical facilities are not available. The patient is placed in the true Fowler's position at an angle of 30 degrees with the floor, hot fomentations are applied to the abdomen in order to assist in the resolution of the mass, nothing is given by mouth, and sedatives are given to relieve pain. If this procedure is followed, the mortality is lower, and subsequent removal 3 months later may be carried out safely.

Postoperative Care

In the uncomplicated cases there is remarkably little postoperative treatment. Patients are encouraged to get up the next day and to lead as normal a life as possible.

In those cases with a localized abscess or generalized peritonitis, the patient is placed in Fowler's position and gastric suction or, better, intestinal drainage by means of a tube is used to prevent distention of the bowel and the development of adynamic ileus. Change of posture, complete abstinence from food and fluids by mouth, and the intravenous administration of fluids and electrolytes also aid in accomplishing this result. Any attempt to stimulate the paralyzed bowel by drugs or surgery is futile.

SUBACUTE APPENDICITIS

Subacute appendicitis is a convenient term to describe those cases which are milder than the acute form and may include recurrent ap-

pendicitis. There is no practical way of correlating these milder forms with etiologic causes or pathologic classifications except to say that they will include catarrhal, exudative, proliferative, and productive inflammation, but exclude suppurative, ulcerative, and obstructive inflammation and necrosis of the appendix.

RECURRENT APPENDICITIS

The term chronic appendicitis, while in wide use in medical circles, should be reserved for the specific granulomas such as tuberculosis or actinomycosis. Vague symptoms of pain in the right lower quadrant, often ascribed to chronic appendicitis, are frequently not relieved by removal of the appendix.

However, the changes that occur in the appendix during an acute attack predispose to recurring infections. In recurrent acute appendicitis the symptoms are similar to those described under the acute form, although milder in degree, and between attacks the patient may be free of symptoms. If this clinical picture presents, the diagnosis is not in doubt and the patient will be cured by removal of the appendix.

More common is recurrent appendicular colic. Fecaliths or other foreign bodies contained within the appendix cause excessive peristalsis in the organ as it attempts to expel the object. Colicky spasm felt in the right lower quadrant of the abdomen, associated with deep tenderness on palpation in this area, will confirm the diagnosis.

ACTINOMYCOSIS OF THE APPENDIX

The second commonest site of actinomycosis is the right iliac fossa, although in comparison with other causes of appendicitis it is a rare disease. The patient usually presents after several days or weeks with a mass and tenderness in the right iliac fossa. At operation an abscess is found with pus containing yellow sulfur granules. If these are squeezed between two microscope slides, the ray fungus can be identified with a microscope in the theater. Removal of the appendix is carried out, the abscess is drained, and large doses of penicillin in combination with streptomycin or other antibiotics are administered.

TUMORS OF THE APPENDIX

Benign

The general incidence of new growths of the appendix is low, consisting of about 0.5% of all intestinal growths; but the appendix may be frequently involved in secondary neoplasms. The simple tumors, all of which are rare, include fibroma, myxoma, lipoma, angioma, and adenoma. This last is more common than the others, is usually associated with the symptoms of mild appendicitis, and is an accidental finding at operation.

Malignant

Primary malignant tumors of the appendix are uncommon. Adenocarcinoma occurs but is rare. Of more importance is the carcinoid tumor. These occur in the appendix and in the small bowel. The location of the tumors is of some importance, for if in the appendix they are of low malignancy and do not metastasize, while those in the small intestine may be multiple, produce obstruction to the bowel, and metastasize to the regional lymph nodes.

Carcinoid tumors of the appendix usually cause no symptoms, and the diagnosis is made only at operation. They produce a firm localized swelling in the appendix and appear light yellow on their cut surface. Microscopically, the tumor consists of masses of spheroidal

cells which are rich in lipid. According to Masson they are chromaffinomas.

The treatment is resection. Recurrence of carcinoid tumors of the appendix is rare, and the prognosis is excellent.

Title

Diseases of the Appendix (A photographic supplement for clinics or conferences) (1953) (By Hilger P. Jenkins, M.D., and Douglas Packard, M.D., Chicago)

Colon

Harry S Morton, MB

HISTORY

The history of colonic surgery began in the 18th century when Littre suggested colostomy for obstruction in 1710, and Pillore performed it successfully 66 years later.

During the next hundred years the mortality for resection prevented progress, but when surgeons turned to exteriorization, peritonitis was reduced. Mikulicz in 1903 popularized and gave his name to this method which had been independently developed by Bloch and by Paul. During the first part of the century this treatment was mainly used for tumors, and when it was applied to gunshot wounds of the colon during World War II, the extremely high mortality was immediately reduced to approximately 25%.

The postwar development of preoperative colonic preparation helped to make possible resection for tumors and diverticulitis. Intravenous therapy and intraluminal suction are other factors which have assisted in the lowering of mortality.

ANATOMY

The large intestine begins in the right iliac fossa as a blind pouch known as the cecum which extends about $2\frac{1}{2}$ " below the ileocecal junction. It then continues as the ascending colon, the hepatic flexure, the transverse colon, the splenic flexure, the descending colon, the sigmoid, and finally ends at the peritoneal reflection in the pelvis.

The ascending and descending colon and the two flexures are fixed posteriorly and covered by the peritoneum, except on their posterior aspect. The transverse colon and the sigmoid, on the other hand, have mesenteries which permit wide mobility. The total length of the large bowel is usually 5', approximately one fifth that of the alimentary canal. The diameter gradually diminishes from about $2\frac{1}{2}$ " in the cecum to $1\frac{1}{2}$ " in the sigmoid.

The wall of the large intestine consists of five layers. There is a lining mucous membrane of single columnar cells which are arranged into the crypts of Lieberkuhn. Under this is the submucosa containing the vessels, nerves, and lymphatics. Next comes the circular muscle coat. The longitudinal muscle fibers are characteristically collected into three bundles called the taeniae. These are about one sixth shorter than the remainder of the intestine, and therefore the wall is puckered into large sacculations. The outermost layer is the serosa or visceral peritoneum covering the appendices epiploicae which consist of fat and blood vessels. The taeniae and appendices epiploicae are particularly characteristic of the large bowel.

Blood Supply

Blood is supplied to the colon from two sources. The superior mesenteric artery gives off the middle colic artery and the right colic artery. This latter vessel divides into two branches, the descending branch anastomoses

with the terminal branch of the superior mesenteric artery in the ileocecal region; the ascending branch anastomoses with the right branch of the middle colic artery. The left colic artery arises from the inferior mesenteric artery near its origin and passes upward and to the left, where it divides into ascending and descending branches. The ascending branch anastomoses with the left branch of the middle colic artery near the splenic flexure, while the descending branch anastomoses with the first sigmoid artery. This series of anas-

1-6 and anastomose with each other in arcades. There is a second series of smaller arches before the short straight arteries enter the sigmoid in the same manner as in the rest of the colon. The architecture of the vessels in the sigmoid is therefore similar to that of the small bowel.

The length of the sigmoid arcades is of fundamental importance in proctosigmoidectomy because it is only when the arcades are long that it is possible to mobilize the sigmoid down to the anus and preserve the blood supply.

Fig. 338.—Normal arterial supply and lymphatic drainage of colon

tomoses near the colon forms the marginal artery. All these branches give off short straight vessels to supply the colon. As they approach this organ, they divide into two branches which penetrate the muscle wall. Finer branches move around the surface to supply both the muscle and mucosa near the two anterior taeniae. The openings for these vessels through the circular muscle coat frequently cause weakness in this layer, particularly on the left side. The sigmoid arteries vary in number from

The arterial architecture is accompanied by the venous tributaries, the lymphatic drainage, and sympathetic nerves. Many surgeons believe that the blood supply determines the extent of the surgery that can be performed, but it has been found in practice that end-to-end anastomosis can be executed in any part of the large bowel, and the blood supply is better than was previously believed to be the case, provided the patency of the marginal artery is preserved.

Lymphatic Drainage

The lymphatic drainage begins in the sub-mucosal layer with the vessels forming a network which drains into numerous nodes along the posterior aspect of the colon and in the mesentery. These nodes in turn drain by vessels to other nodes in the middle of the mesentery and finally into the para-aortic nodes. The limiting factor to cancer surgery is involvement of the para-aortic nodes by the growth which makes them adherent not only to the abdominal aorta but also to the inferior vena cava. Therefore surgery, to be successful, must be carried out before the disease has spread to these nodes.

PHYSIOLOGY

One function of the colon is to concentrate the feces by removing water. The size of the colon varies with the diet of the individual animal. Meat-eating animals have very little need for a colon because digestion has been completed in the small bowel. It is therefore only necessary for the water to be absorbed from the feces. In herbivora, on the other hand, digestion of cellulose products takes place in the colon, and there is usually a large cecal pouch where digestion may continue for a long time. Man's colon is designed for an omnivorous diet. It is slightly sacculated as in some of the herbivora, and the length is suitable for the digestion of a moderate amount of cellulose.

Movements of the Colon.—It is extremely difficult to observe peristaltic movement of the large intestine either at operation or during radiologic studies. Occasionally a sudden movement may be observed on the fluoroscope, when the contents of the right half of the colon move over to the left half in a matter of seconds. This is called *mass movement* and usually occurs after a meal, in association with the gastrocolic reflex. There is a relaxation of tonic action of the musculature, the haustral markings disappear, and the colon becomes a smooth tube. Then a large peristaltic wave sweeps the whole contents along.

The Nerve Plexuses.—The nerve plexuses are arranged in a somewhat similar manner to those in the stomach. In fact there appears to be a closer association between the central

nervous system and both the stomach and the large bowel than with the small bowel. The autonomic nervous supply consists of the sympathetic and parasympathetic nerves; the sympathetic follow the blood vessels to the large bowel, while the parasympathetic are the vagus, and the sacral outflow from S2 and S3. So far as is known the vagus supplies the right half of the colon almost to the splenic flexure, and the sacral outflow the left half of the colon. The numerous plexuses in the colonic wall are still being debated, as there are more than those described by Auerbach and Meissner.

EMBRYOLOGY AND CONGENITAL ANOMALIES

(See Chapter 30.)

FOREIGN BODIES

Swallowed foreign bodies commonly pass through the alimentary canal; occasionally they may become lodged in the colon, usually the sigmoid; they may also be introduced from below or travel from an adjacent structure. Several factors contribute to the lodgment of foreign bodies in the sigmoid colon since it is sacculated, may contain diverticula, its lumen is narrower, and there is a physiologic sphincter at the rectosigmoid junction. Those introduced from below seldom get beyond the rectum. Penetrating foreign bodies are rare, but occasionally impaling accidents may cause them to break off and remain in the lumen.

The symptoms are extremely variable. There may be pain, hemorrhage, constipation or diarrhea, or the complications of infection or genitourinary tract involvement.

Treatment.—Unless peritonitis has occurred, the treatment is expectant, as most foreign bodies will pass spontaneously. If peritonitis results from perforation of the bowel, laparotomy must be performed. Rectal perforation may result in a pelvic cellulitis which should be drained.

WOUNDS AND INJURIES OF THE COLON

External violence from blunt instruments seldom causes injury to the colon because of its mobility and elasticity, while that from

knife wounds may cause lacerations of the abdominal wall without necessarily injuring the adjacent bowel wall. On the other hand, gunshot and especially high velocity missiles cause jagged perforations with marked contusion of the surrounding bowel wall, which necessitate exteriorization. Such injuries are not suitable for closure by suture.

When an individual is near the blast of an explosion the intestine containing gas is often perforated. This is due to the rapid acceleration of the compression wave at the interface between solid and gas and to the tearing force of the confined gas. In civilian practice, workers using compressed air nozzles may cause damage to the colon, whether by accident or horseplay, when the nozzle is brought near the anus. This is an extremely dangerous accident since the compressed air, passing harmlessly through the clothing, seldom injures the anus and rectum which are well supported, but causes blowout of the splenic flexure or cecum, the seriousness of which may not be recognized for several hours.

The symptoms of perforation of the colon are pain and localized tenderness. Later there are the signs of peritonitis—nausea, vomiting, boardlike rigidity, and shock. The spread is rapid throughout the peritoneal cavity, and the critical time period is approximately 6 hours.

Treatment.—The shock must be treated quickly by raising the foot of the bed and by giving vasopressors and blood transfusions. The keynote of colonic surgery in military perforations is exteriorization of the damaged gut. Lacerations require suture and proximal defunctioning colostomy.

MESENTERIC CYSTS

Mesenteric cysts may be classified into

- 1 Developmental
 - a Enterogenous
 - Chylous
 - c Lymphatic
- 2 Traumatic, usually hematomas
- 3 Inflammatory, such as
 - a Mesenteric adenitis
 - b Tuberculous adenitis
 - c Hydatid
- 4 Neoplastic
 - a Dermoid cysts
 - b Teratomas

Enterogenous cysts are usually single and attached to the intestine at one point, with a wall consisting of all the layers of the bowel. The cavity contains clear mucoid fluid, usually opalescent, but it may be thick and opaque. These cysts arise as localized duplications of the bowel but cause symptoms only in adult life. They are usually found near the cecum and ascending colon.

Chylous cysts contain thick inspissated material resembling chyle; the wall is of thick fibrous tissue with an endothelial lining and a round cell infiltration with occasional giant cells.

Lymphatic cysts are thin walled, are frequently multiple and multilocular, and have clear contents.

Clinical Picture.—The clinical picture is a vague mobile abdominal mass in a young adult, giving rise to indefinite symptoms. The size varies but may be considerable. The cysts are usually painless unless the complications of infection, adhesions, rupture, hemorrhage, or intestinal obstruction occur.

Treatment.—The treatment is removal, and this can often be done without interfering with the blood supply to the bowel. Should this prove to be impossible, then resection of the affected bowel and its mesentery is indicated.

VOLVULUS

Volvulus is a torsion of an abnormally mobile loop of bowel on its axis, usually resulting in obstruction. This most often occurs in the sigmoid region because of the length of its mesentery. The cecum may be affected, but only if there has been failure of attachment and it is freely mobile with a mesentery, as mentioned in the second anomaly of malrotation (see Fig. 395). This condition is commoner in inmates of mental institutions than in the general population.

Clinical Picture.—The picture is one of acute severe intestinal obstruction. The abdominal distention is marked, and copious vomiting occurs, with early dehydration and shock, particularly if strangulation of the involved loop has developed. There is frequently a history of similar but less severe attacks of pain from which the patient has recovered.

A flat film of the abdomen will show greatly dilated loops of bowel, and it is frequently possible to ascertain the area of volvulus by the position of the most dilated loop.

Treatment.—If one or two enemas do not relieve the torsion, laparotomy is indicated with untwisting of the involved loop of bowel. When strangulation has occurred, resection is obligatory. As the volvulus may recur following untwisting, colopexy or resection is frequently advocated. In all cases the accompanying shock and dehydration must be corrected by intravenous fluids, electrolytes, and whole blood transfusions.

Fig. 339.—Acute intestinal obstruction due to volvulus of the sigmoid. Note the marked unequal distention of the sigmoid loop. The markers indicate the adjacent walls of the distended loop.

DISEASES OF THE APPENDICES EPIPLOICAE

The appendices epiploicae are localized, peritoneal-covered outgrowths of fat from the wall of the large bowel and are one of the main characteristics of the colon. Their number varies enormously and may be in excess of two hundred. They are most numerous in those areas with a mesentery, namely, the

transverse and sigmoid colon, and are arranged in two parallel rows adjacent to the anterior and posterior longitudinal taeniae. One of these appendices may become twisted, causing a sudden sharp abdominal pain which is referred to the right side of the abdomen. Vomiting, tenderness, and rigidity are present, giving the picture of an acute surgical condition which may be mistaken for appendicitis, cholecystitis, or diverticulitis. The treatment is surgical removal. The appendices epiploicae may become adherent to other abdominal contents and cause intestinal obstruction. This is usually a late result of infection. No definite symptomatology can be given.

DIVERTICULOSIS

True and false diverticula occur in the large bowel, the former are rare, amounting to less than 1%, and occur in the proximal half of the colon. Their walls consist of all the layers of the bowel. False diverticula generally occur in the distal portion, are nearly always multiple, and consist of a herniation of the mucosa through the musculature, usually where the vessels penetrate the wall. They are caused by increased intraluminal pressure. They are frequently seen in barium studies of the colon and do not cause any symptoms.

Pathology.—Diverticula are found in 10% of persons over 40 years of age. If the opening of the sac into the intestine is large, symptoms will rarely develop, as the sacs empty. However, when the openings are small, the contents of the bowel enter the false diverticula and may become lodged there, leading to ulceration of the walls and the production of diverticulitis.

DIVERTICULITIS

Inflammation in a false diverticulum is diverticulitis. The signs and symptoms are those of localized intra-abdominal inflammation, pain, tenderness, and rigidity, usually in the left lower quadrant of the abdomen. Perforation of a diverticulum may result in a localized abscess or generalized peritonitis.

If an abscess develops, a tender mass will be palpable. The abscess may rupture, causing generalized peritonitis, or it may communicate with adjacent bowel or bladder, resulting in a

fistula. These fistulas may be internal or external onto the skin of the abdomen or perineal region. Because of the age of the patients, it may be difficult to rule out malignancy, and careful investigation must be carried out. Occasionally the inflammatory process may obstruct the lumen of the bowel.

In establishing the diagnosis, sigmoidoscopic examination, though it gives little positive information, may help to eliminate the possibility of cancer. The barium enema shows the many diverticula, and the narrowing of the lumen in peridiverticulitis is longer and more tapered than in stenosis from cancer. Diverticulosis and carcinoma, however, are both common diseases in the older age group. They not infrequently occur together, and the final determination may be only at laparotomy and by pathologic examination.

Fig. 340—Complications of diverticulitis. An analysis of 103 cases showing how the various complications arise.

Treatment.—Unless complications arise the treatment is conservative. This includes a low residue bland diet, mineral oil as the only laxative, and the administration of anticholinergic drugs. The treatment of the complications has recently changed from a conservative to a more radical approach. For perforation with generalized peritonitis, drainage of the peritoneal cavity with the administration of local and systemic antibiotics is routine. Obstruction and fistula formation require a proximal defunctioning colostomy, usually in the transverse colon, later followed by resection and subsequent closure of the colostomy. Some

authors advocate resection even earlier in pericolicitis, in local abscess, and in the chronic stage, in the hope of preventing the more serious complications.

ULCERATIVE COLITIS

Etiology.—By definition the cause of non specific ulcerative colitis is unknown. Various theories have been advanced. Some authors have supported an infective etiology—any of the normal flora of the colon may penetrate the mucosa and initiate minute inflammatory foci. Others believe it to be an allergic phenomenon, but this has been confirmed only in about 10% or less of the cases. The psychiatrists state that the patients are usually psychologically dependent on one member of the family group, that they are frustrated and not ambitious. These mental conflicts are transmitted through the vagus nerve to the colon, where it has been demonstrated that the impulses affect the blood supply causing first ischemia, later followed by a marked congestion. On the other hand, most authorities are still in doubt whether this psychologic theory is a cause or an effect. Some have suggested a vitamin deficiency and others, neurovascular imbalance. Another theory involves enzymes, such as lysozyme, while still another concerns the relationship of metabolic derangements of the steroids and related hormones.

To simplify this complicated etiology, it would seem wise to combine these theories into a composite picture. In persons with a certain psychologic pattern impulses may pass down the parasympathetic to the colon, thereby altering the blood supply and allowing the normal bacterial population better access to the mucosa. The congestive phase favors aerobic organisms, the ischemic phase anaerobic, so that infection is a secondary manifestation in an already abnormal bowel. The stimulation of the vagus nerve increases the motility, which fractures the friable mucosa, producing ulceration. The steroids and enzymes further influence the metabolic derangements. With the presence of ulceration there is the loss of absorption, vitamin deficiency, and alteration of nutrition, with resulting further diarrhea and the setting up of a vicious cycle.

fistula These fistulas may be internal or external onto the skin of the abdomen or perineal region. Because of the age of the patients, it may be difficult to rule out malignancy, and careful investigation must be carried out. Occasionally the inflammatory process may obstruct the lumen of the bowel.

In establishing the diagnosis, sigmoidoscopic examination, though it gives little positive information, may help to eliminate the possibility of cancer. The barium enema shows many diverticula, and the narrowing of the lumen in peridiverticulitis is longer and more tapered than in stenosis from cancer. Diverticulosis and carcinoma, however, are both common diseases in the older age group. They not infrequently occur together, and the final determination may be only at laparotomy and by pathologic examination.

Fig 340—Complications of diverticulitis. An analysis of 103 cases showing how the various complications arise.

Treatment.—Unless complications arise the treatment is conservative. This includes a low-residue bland diet, mineral oil as the only laxative, and the administration of anticholinergic drugs. The treatment of the complications has recently changed from a conservative to a more radical approach. For perforation with generalized peritonitis, drainage of the peritoneal cavity with the administration of local and systemic antibiotics is routine. Obstruction and fistula formation require a proximal defunctioning colostomy, usually in the transverse colon, later followed by resection and subsequent closure of the colostomy. Some

authors advocate resection even earlier in pericolicitis, in local abscess, and in the chronic stage, in the hope of preventing the more serious complications.

ULCERATIVE COLITIS

Etiology.—By definition the cause of no specific ulcerative colitis is unknown. Various theories have been advanced. Some authors have supported an infective etiology—of the normal flora of the colon may penetrate the mucosa and initiate minute inflammatory foci. Others believe it to be an allergic phenomenon, but this has been confirmed only in about 10% or less of the cases. The psychiatrists state that the patients are usually psychologically dependent on one member of the family group, that they are frustrated and not ambitious. These mental conflicts are transmitted through the vagus nerve to the colon, where it has been demonstrated that the impulses affect the blood supply causing first ischemia, later followed by a marked congestion. On the other hand, most authorities are still in doubt whether this psychologic theory is a cause or an effect. Some have suggested a vitamin deficiency and others, neurovascular imbalance. Another theory involves enzymes, such as lysozyme, while still another concerns the relationship of metabolic derangements of the steroids and related hormones.

To simplify this complicated etiology, it would seem wise to combine these theories into a composite picture. In persons with a certain psychologic pattern impulses may pass down the parasympathetic to the colon, thereby altering the blood supply and allowing the normal bacterial population better access to the mucosa. The congestive phase favors aerobic organisms, the ischemic phase anaerobic, so that infection is a secondary manifestation in an already abnormal bowel. The stimulation of the vagus nerve increases the motility, which fractures the friable mucosa, producing ulceration. The steroids and enzymes further influence the metabolic derangements. With the presence of ulceration there is the loss of absorption, vitamin deficiency, and alteration of nutrition, with resulting further diarrhea and the setting up of a vicious cycle.

Plate 29.—Diverticulosis and Diverticulitis.

Plate 30.—Ulcerative Colitis.

Clinical Picture.—Nonspecific ulcerative colitis usually presents between the ages of 20-40 years but may occur at any age, and the sexes are almost identically affected.

In the true form of recurrent ulcerative colitis the attacks begin with severe diarrhea, with frequent stools up to 15-20 a day, lasting more than a week. The diarrhea is associated with pain, malaise, weakness, loss of appetite, and loss of weight. The patient is pale, the eyes sunken, the abdomen slightly tender with no palpable masses, and the temperature is elevated. On sigmoidoscopic examination the colonic mucosa is red, granular, and bleeds easily to the touch, and pinpoint ulcers may be found. These pinpoint ulcers gradually enlarge until the muscle coat is exposed. Between the ulcers the remaining mucosa is engorged and edematous, forming pseudopolypi which occasionally may become malignant. The ulcers have even been noted to arrange themselves in three longitudinal bands in extensive cases. Radiologic examination of the large bowel by barium enema shows an irritated, hyperactive colon with loss of normal haustration. In the more advanced cases, it has a "pipe-stem" appearance, and ulcers are seen. Laboratory tests reveal low plasma proteins, and in severe cases the liver function is impaired.

Complications.—The *minor* complications are hemorrhoids, fissures, pruritus, hypertrophic osteoarthropathy, and infantilism. The *major* complications are pseudopolypoidosis, stricture, perirectal abscess, fistula, perforation, and carcinoma.

Differential Diagnosis.—The diagnosis of this disease is one of exclusion. At the time of sigmoidoscopic examination a swab culture is taken from the mucosa in order to exclude *Entamoeba histolytica* and the organisms of Shiga and Flexner which cause bacillary dysentery. Sigmoidoscopic examination will be negative for the 10% of the cases in which the disease is confined to the proximal colon, but this will be demonstrated by a barium enema. This examination will also determine the extent and stage of the disease. Malignant changes can only be excluded by biopsy and supervene in about 5% of cases.

Treatment.—Medical treatment consists of blood transfusions and iron therapy for anemia,

increased fluid intake to overcome dehydration, supplementary feedings of high protein milk-shakes, and vitamins, particularly B and C. Intestinal sedatives should be given, such as atropine, hyoscine, and phenobarbital. Recently 100 mg. of cortisone daily for a week has been used. This therapy is successful in more than half of the cases. A further 20% will be continued on medical treatment but with definite impairment of function. About one quarter of the patients will require surgical intervention.

Indications for Surgery.—The surgical therapy of ulcerative colitis should be restricted to only the most carefully selected cases. For this purpose ulcerative colitis is divided into three groups:

Group I. Those patients with fairly mild symptoms who respond well to medical therapy and those cases in which the disease does not prevent regular attendance at work or interfere with the daily routine of life.

Group II. Those patients with moderately severe symptoms, with only fair response to medical treatment, frequent exacerbations of symptoms, and a reduction of activity. This group is also subject to the complications or sequelae of the disease which are as follows:

- 1 Perforation of the distended colon
- 2 Stricture formation
- 3 Massive hemorrhage
- 4 Fistula formation
- 5 Abscess formation
- 6 Chronic inanition
- 7 Psychologic changes
- 8 Pseudopolypoidosis
- 9 Malignant change

Group III. The fulminating type. These patients develop an extremely severe type of the disease, with almost continuous diarrhea, hemorrhage, abdominal pain, dehydration, and rapid wasting.

Operative treatment of ulcerative colitis should be reserved for patients in Groups II and III. Group III patients should be prepared for operation by concerted efforts to improve the nutritional status, restore the blood volume, and reduce the pain and secondary infection. It may be necessary to operate on a woefully ill patient, but this is frequently the only means of saving life.

Group II patients, of course, require surgery for the complications of the disease. However, some Group II patients without complications

require operative treatment, although great care in selection must be taken. We consider that operation is indicated under the following conditions:

1. If there is loss of time from work
2. If pleasures or social activities are affected
3. If pathologic changes develop

In any case, an ileostomy should not be performed until it becomes a most welcome relief from the tortures of the disease. It is our experience that if the ileostomy is done early in these so-called intractable cases, the patients do not become psychologically adjusted to the ileostomy and are a continual problem for the surgeon. On the other hand, when the escape from a hitherto intolerable situation is given by ileostomy (and colectomy), the relief of the patient is such that he never wishes to go back to his old way of life.

Operative Treatment.—The operative treatment of ulcerative colitis has been unsuccessful in the past. Many different-staged procedures have been recommended. Except from a historic point of view, it would now appear unnecessary to mention them—appendicostomy, cecostomy, and internal defunctioning anastomosis.

Ileostomy.—This alone carries with it a mortality of 15-20%. It does not remove the disease and has been recommended in the past as a primary procedure to be followed in convenient stages by a right, then a left, hemicolectomy, and finally abdominoperineal resection.

Partial or Subtotal Colectomy.—When medical treatment fails, the patients with fever, dehydration, anemia, continuing diarrhea, and blood, pus, and mucus in the stool should be prepared for operation by intensive intravenous therapy, including blood transfusions, supplementary feedings by mouth, sulfonamides, antibiotics, and intestinal sedatives. The hemoglobin should be at least 80% and the plasma proteins within normal limits. Then an ileostomy combined with a subtotal colectomy should be carried out in one stage. This procedure eliminates the toxic absorption from the diseased bowel and the protein and the red cell loss in the bowel exudate. The mortality from this procedure is much less than from ileostomy alone, even in fulminating cases, but it is important that this surgical procedure should be

carried out early enough to be lifesaving. Some surgeons have attempted, in the very severe cases, to do a total colectomy with abdominoperineal resection in one stage. This, however, carries a high mortality and would seem to be too extensive.

A small proportion of cases, where the disease is limited to the proximal colon, may have a subtotal colectomy and an ileosigmoid anastomosis. Otherwise, the patients have to carry a permanent terminal ileostomy. The question is often raised whether it is possible to close the ileostomy and join it to the remaining sigmoid, rectum, or anus. This is possible if the distal portion of the bowel is stretched to an adequate diameter, if the disease is under control, and if the anastomosis is made distal to the sacral parasympathetic outflow.

Vagotomy.—In early cases, vagotomy has been advocated, particularly if the disease is limited to the proximal colon.

Abdominoperineal Resection.—This should be carried out if the disease process persists in the distal remaining segment.

Prognosis.—The patient with an ileostomy and a total colectomy can resume normal activity. There is no difficulty in maintaining satisfactory nutrition on a normal diet. The mortality for this procedure is less than 5%.

INTUSSUSCEPTION IN ADULTS

The year 1751 marks the beginning of our knowledge of adult intussusception. Nuck first made the diagnosis in a female of 50 years; and Velse and Bonetus each operated on adults for this condition. By definition it is an invagination of a proximal portion of the bowel (the intussusceptum) into a distal portion (the intussusciens).

Pathology.—Almost any area in the large or small bowel may be the site of an intussusception. It usually occurs singly, although occasionally compound, multiple, retrograde forms have been reported, particularly in the colon. The following types are usually described:

1. Ileocecal—where the apex of the intussusception is the ileocecal valve
2. Ileocolic
3. Jejunocolic
4. Ileocolocolic
5. Colocolic
6. Jejunogastric
7. Gastroduodenal

} These forms constitute a classification of anatomic sites

} These occur in association with simple tumors of the stomach

Once the intussusception becomes established, edema of the bowel sets in and there is peritoneal exudate, blood vessel strangulation, and finally gangrene if the condition remains unrelieved. In a few cases, spontaneous reduction may occur, the process may become chronic, or the intussusceptum may slough and be passed per rectum.

Etiology.—In contrast to the unknown etiology in children, the cause in the adult is usually a tumor in the wall, such as a submucous lipoma, a papilloma, or carcinoma of the colon.

typical "cupola" outline at the head of the barium mass

Treatment.—The treatment of choice is laparotomy and reduction of the intussusception by taxis, that is, by compressing the apex backward. If this is at all difficult, then resection with end-to-end anastomosis should be carried out. In the adult, there is nearly always an organic lesion as the underlying cause, which should be excised. If, however, carcinoma is found then the principles of cancer surgery are employed

(See also Chapter 30, Pediatric Surgery.)

Fig 341—Intussusception of carcinoma of the ileum into the colon in a female patient, aged 50 years

A, With barium B, Postevacuation

Clinical Picture.—The clinical picture is usually that of intestinal obstruction with the gradual onset of crampy abdominal pain, nausea, and vomiting. In the enteric group this occurs at an earlier stage than in the colonic cases, where the process is less acute and consists of obscure abdominal pain associated with an ill-defined mass

Investigation should always include a rectal examination and a search for blood, particularly in the colonic group. A barium enema will be helpful in establishing the diagnosis, with the

SPECIFIC INFECTIONS OF THE COLON

Tuberculosis

Tuberculosis is becoming steadily less common. When it occurs it affects the ileum and is due to swallowed tubercle bacilli in a patient with pulmonary tuberculosis. In the region of the cecum it usually causes a large inflammatory mass which is palpable. It can be confused pathologically and clinically with regional ileitis.

The treatment is a short-circuiting operation, or resection with subsequent anastomosis

Actinomycosis

Abdominal actinomycosis commonly affects the cecum, terminal ileum, and appendiceal regions. It cannot be recognized preoperatively unless there are sinuses, when the ray fungus can be demonstrated in the discharge.

The treatment is surgical removal and chemotherapy

Amebiasis

Amebiasis is of importance because of both its local and distant manifestations. There is a chronic thickening of the colonic wall, with dysenteric ulcers of varying size, usually having a ragged undermined edge and a slough covering the floor containing the ameba. The later cicatrizing cases present as chronic intestinal obstruction and must be distinguished from carcinoma. There is a thick edematous swelling of the wall, longer than in malignancy, frequently multiple, and without ulceration, while the malignant lesion is firm, short, single, friable, and ulcerated. When amebiasis is diagnosed, the treatment with emetin gives dramatic results.

The distant manifestations are amebic abscess of the liver with the "anchovy sauce" contents, which must be drained. Rarely is there an abscess of the brain or lung.

BENIGN NEW GROWTHS

All varieties of benign growths may be found in the colon, the most common being lipomas and adenomas. The fibroadenoma is frequently seen as a multiple polyposis, either congenital or acquired. The rarer growths are angiomas, fibromas, and myomas. These new growths may give rise to bleeding, diarrhea, and occasionally pain.

Multiple Polyposis

The pedunculated adenomatous polyp may be either single or multiple, and it usually occurs in the distal portion of the large bowel. Such polyps have a marked tendency to become malignant. In fact, the comparative distribution of carcinoma is so strikingly similar

that the removal of the area containing the polyps amounts to a prophylactic cancer operation.

Treatment.—The small sessile adenomas may be removed by cauterization. Pedunculate polyps are cauterized, including the entire base. Large sessile adenomas must be excised.

Villous Papilloma

Long, thin, delicate branching finger processes projecting from the surface, the pile of a velvet carpet, are much more numerous than the other forms and require radical removal.

Pseudopolyposis

This exuberant inflammatory mucosal proliferation between the ulcers of ulcerative colitis usually occurs in the more chronic forms of the disease, both specific and non-specific. The incidence of carcinoma developing in pseudopolyposis varies from Thorlakson's 6% to Duke's 50% in those cases of over 10 years' duration. The indication for colectomy in such cases is therefore clear.

Familial Polyposis

Familial polyposis is a relatively rare condition characterized by the appearance of multiple adenomatous polyps in the colon and rectum. It is termed familial because it is transmitted from one generation to the next usually as a mendelian dominant, although occasionally as a recessive character. Although polyps may be present at birth, they usually appear later, producing symptoms between 15-40 years of age. Rarely, the condition exists throughout life without causing symptoms.

Diagnosis.—Except when the family history of the condition is known and an apparently well member of the affected family is examined specifically for the presence of polyps, the diagnosis is made after symptoms of complications develop. Common symptoms are (a) bleeding by rectum, (b) intussusception, (c) protrusion of a low-lying polyp from the anus, and (d) bowel obstruction, chronic or acute, as a rule due to a carcinoma developing in a polyp.

Plate 31.—Benign Tumors Multiple Polyposis

Almost invariably the diagnosis can be made by rectal and sigmoidoscopic examinations. The barium enema x-ray examination, particularly with air-contrast technique, will reveal the presence of the polyps in the bowel above the reach of the sigmoidoscope, provided they have reached sufficient size. When malignant degeneration of a polyp has occurred, the findings will be those of carcinoma of the colon or rectum.

Treatment.—Because each of the multiple polyps bears malignant potentialities, almost every individual with familial polyposis will sooner or later develop carcinoma of the

to the remainder of the rectum; after the latter operation removal of benign lesions in the remainder of the rectum by fulguration through a proctoscope.

The rectum must be resected when the rectal polyps are very large and too numerous for safe removal by fulguration.

MALIGNANT TUMORS OF THE COLON

Carcinoma of the colon is apparently becoming more frequent because of two factors: the increasing accuracy of diagnosis and the lengthening span of life. During the 20th

Fig 342—Dukes' concept of adenoma and papillary adenoma formation

bowel. For this reason prophylactic excision of abnormal mucosa is necessary. Not only does the individual concerned have to be treated, but the other members of the family should be thoroughly investigated.

There are two principal methods of treatment of multiple polyposis before malignant degeneration has occurred:

1. Excision of the cecum, appendix, colon, and rectum, with the establishment of a permanent ileostomy.
2. Excision of the colon and upper portion of the rectum, with anastomosis of the ileum

century, this has increased by 15-20 years, so that a larger number of people are entering the cancer age.

Carcinoma of the large bowel is a common disease, accounting for 10% of all cases of cancer.

The site of the growth in the large bowel depends on the accurate definition of the recto-sigmoid. In order to overcome individual interpretation of this area, it is better to consider the colon and rectum as one unit. The following table shows the proportional involvement by site in this hospital.

COLON

DISTRIBUTION BY SITE

Cecum	7%
Ascending colon	10%
Transverse colon	14%
Descending colon	5%
Sigmoid	21%
Rectosigmoid	7%
Rectum	36%

Etiology.—The origin of cancer of the colon is not known, but there are several predisposing conditions to cancer in this site. Of these, the most important is familial multiple polyposis, which invariably becomes malignant. Single isolated polyps may occasionally undergo malignant change, while pseudopolyposis becomes cancerous in approximately 2-3% of cases. Diverticulitis and cancer of the colon coexist in from 3-5% of cases.

Pathology.—There are two main types of carcinoma in the colon. The commoner is the annular stenosing obstructive growth which is more frequent on the left side of the bowel. The proliferative cauliflower-like papillary variety occurs characteristically on the right half of the colon. They are both adenocarcinomas. Colloid or mucoid degeneration occurs in about 5% of cases.

Benign polyps may have a malignant change at their tip which can be called a carcinoma-in-situ. Invasive carcinoma arising in the polyp will show changes in the ground substance, but the growth may still remain outside the lamina propria. If the growth occurs at the base rather than at the tip of the polyp, it is more dangerous for two reasons: it is nearer to the lamina propria and, second, local removal is liable to failure because a portion of the malignant growth may be left. The next boundary line is the muscularis mucosae, then the layer of circular musculature. Malignant cells may be picked up in either the lymphatics or blood vessels from the lamina propria on ward. The grading of pathologic types by Broder's classification or Dukes' stages is of some value. No staging can be accurately done without pathologic assistance. The present convention of staging as applied to the rectum could be conveniently applied to the colon.

Stage A—Confined to the mucosa
1 Carcinoma in-situ
2 Carcinoma invasive

Stage B—Involving circular musculature

Stage C—Local lymphatic glands involved but removed surgically

C—More distant lymphatic glands involved possibly surgically removable

Stage D—Generalized dissemination of malignant disease

The spread of carcinoma of the colon is usually by the lymphatics, but the other routes should not be forgotten; namely, by direct spread, along the lumen, implantation, and by means of the blood stream carrying the cells to the liver. This latter method is not quite as common in the colon as in the rectum. It is earlier in the flat sessile growths than in the papillary type. Metastases may also be found in the peritoneum and in the lung.

The rapid venous route of spread is more common than is generally realized. The figure of 15% given 10 years ago has been increased to 40%, and by recent cytologic techniques it was further raised to 60%. It may even be higher. In the hope of controlling these blood-borne emboli, thio-TPA is being administered intravenously at the end of the operation in an experimental series in Chicago.

Passage along the lumen can be prevented by careful handling at operation.

Recurrence of the growth occurs at the line of the anastomosis. This is a result either of inadequate removal or of implantation of cells at the time of operation. The latter complication can be avoided by tying the bowel with umbilical tape above and below the tumor, and irrigating the two cut ends for 5 minutes with a suitable antiseptic fluid before performing the end-to-end anastomosis.

Wangensteen has recently been advocating the second look, which is a deliberate exploration of the abdomen after 6-9 months in those cases of carcinoma of the colon that showed evidence of lymph node involvement at the time of the first procedure.

Clinical Signs and Symptoms.—Carcinoma of the colon is a relatively silent disease, and the early symptoms are vague and indefinite. Consequently it is frequently diagnosed only in the late stages. Vague complaints, such as weight loss and fatigue, must be followed up thoroughly. There is usually some type of dyspepsia, constipation, or mild alteration in the bowel habit, such as a frequency in the desire to defecate. Diarrhea, either spurious or blood

stained, is always worthy of careful investigation, as is anemia, especially if it does not yield readily to medical treatment. Hemorrhage, whether as bright red blood or melena, is classically the commonest symptom. Patients with early hemorrhage have the best prognosis. Pain is usually late but may be the presenting symptom. When cramplike in nature, it is evidence of early obstruction; when spastic or associated with tenesmus, there may be a growth in the distal sigmoid or rectum. Steady pain in the right iliac fossa may be due to distention of the cecum, with a competent ileocecal valve and distal obstruction. A tumor may be felt by the patient or discovered accidentally on routine examination. Any mass without pain in the course of the large intestine must be regarded with grave suspicion.

Right Half of the Colon.—In this segment of the bowel, large cauliflower-like growths are common. These interfere with the normal function of absorption and give rise to anemia, intoxication, or a mass, which may be felt on examination. There may be a mild alteration in bowel habit, and bleeding may occur which should stimulate further investigation. Carcinoma of the transverse colon usually behaves like that in the left half of the colon.

Left Half of the Colon.—Carcinomas in this portion cause the obstructive syndrome. The scirrhous growth spreads in the wall, causing a gradual narrowing of the lumen with the onset of acute superimposed upon a chronic obstruction. This is characterized by visible peristalsis, borborygmi, distention of the abdomen, and pain in the right iliac fossa due to enlargement of the cecum when the ileocecal valve is competent. Progressive constipation is the rule, while blood in the stool, although less common, is of more dramatic significance.

The stools may be small in caliber or contain blood, either macroscopically or microscopically. Pus in association with blood suggests a carcinoma. This vague pattern of many signs and symptoms should be thoroughly investigated in order to establish, or disprove, the presence of malignancy.

Diagnosis.—The diagnosis is made by a careful history. Any alteration in the bowel habits of a patient of the older age group immediately indicates a clinical examination of the abdomen for the recognition of any pal-

pable masses and the noting of any abdominal distention.

This should be followed by digital and sigmoidoscopic examination, although most colonic growths are above the reach of the examining finger and even the sigmoidoscope. Therefore an accurate diagnosis requires a barium enema.

Treatment.—The treatment is entirely surgical. Radiation therapy has little effect, so the only hope is early and complete removal. The preoperative preparation of patients with carcinoma of the colon has been gradually improved due to control of anemia by blood transfusions, of protein metabolism by concentrated feedings, both by mouth and intravenously, relief of distention by Miller-Abbott tube, and the sterilization of the bowel by chemotherapeutic agents. Castor oil and magnesium sulfate should be avoided in preparation of the bowel in ulcerative colitis, regional enteritis, and intestinal obstruction, as violent purgation increases the mortality. In cases of carcinoma, milk of magnesia, 2 drams, should be given. The nonabsorbable sulfonamides are given for 5-6 days before operation, 3 days before operation one of the antibiotics affecting the gram-negative organisms is added. Streptomycin 2 Gm a day, or neomycin 1 Gm every 4 hours for 1 day only, may be used. These are all given by mouth in powder, capsule, or tablet form.

The synergistic action of the sulfonamides and antibiotics will control the flora and allow healing of the anastomosis. The bacterial content of the feces, both aerobic and anaerobic, can be considerably reduced, the only caution being that this should be limited to a 7-day period.

OUTLINE OF PREOPERATIVE PREPARATION OF THE COLON

1 "Sterilization" of bowel:

- a. Sulfathaladine 2 Gm q 4 h for 5 days
- b. Achromycin or 11 Gm bid for 2 days
- neomycin 1 Gm tid for 1 day
- c. Menadione 5 mg bid for 4 days

2 Decompression and cleansing:

- a. Mineral oil 1 oz bid for 5 days
- b. Magnalax daily p.r.n.
- Avoid castor oil
- c. High protein, low residue diet for 2 days prior to operation
- d. Nasogastric suction tube on day of operation

dicating a painful fissure; or a thrombosed external hemorrhoid with its blue, swollen appearance may be seen. In this case further examination must be postponed until after the patient has been anesthetized. Apart from these two painful conditions, digital examination should always be performed. The patient may

the notch between the superficial and deep parts of the external sphincter can usually be felt. Crypts, polyps, and fistulas can be detected. Continuing the rectal examination, the prostate and its consistency is determined in the male, while the pelvic organs are examined in the female. It is convenient to complete

Fig 345B—Diagrammatic anatomy of the rectum

be postured on the left side, or in the knee-chest position. Gentleness and reassurance are necessary at all times. When the finger has been fully introduced, the puborectalis muscle can be palpated posteriorly and laterally and the tone of the sphincters determined. Even

bimanual pelvic examination, especially in children and virgins, by this method. At this time, feces may be found in the rectum; if so, a sample should be removed and examined for color, blood, etc. Next, the finger is swept laterally and posteriorly to examine the coccyx

and lower sacrum for mobility, pain, or other abnormalities. Internal hemorrhoids cannot be felt. *However, more than half of the carcinomas of the colon and rectum lie within reach of the examining finger.*

Examination should be completed by the use of the anoscope, proctoscope, or sigmoidoscope. Before completing this instrumental examination, swabbing of the mucosa may be performed or a specimen of stool collected for culture of organisms. A biopsy may be taken from an ulcer or growth, or fulguration of a polyp may be carried out through the instrument.

Fig 346—Lymphatic drainage of the rectum

CONGENITAL ABNORMALITIES

(See Chapter 30, Pediatric Surgery)

FISSURE-IN-ANO

This painful condition is usually associated with constipation. The scybalous mass tears the anal valve usually in the midline posteriorly, i.e., 6 o'clock, down to the anal verge, thus leaving a raw area or fissure with the subcutaneous sphincter exposed. The patient complains of an internal sharp, stabbing pain on defecation which is caused by spasm of the sphincter. This is often followed by the

passage of a few drops of blood. On examination there is a hypertrophied tag of anal tissue (sentinel pile) usually posteriorly, but in about 10% of cases anteriorly, in the base of which may be seen the lower end of the fissure.

The treatment consists of softening the stool by liquid paraffin and injecting the patient with a local anesthetic in an oil base which should afford relief of pain for approximately a week. If this fails, then under anesthesia, the sphincter is dilated up to four fingers in size, and the fissure and sentinel pile are excised, usually combined with partial severance of the subcutaneous external sphincter.

HEMORRHOIDS

External Hemorrhoids

External hemorrhoids are varicosities of the external hemorrhoidal veins. These form enlargements around the anal margin, and occasionally become thrombosed. The occurrence of this thrombosis is marked by acute pain and the appearance of a firm lump at the anal margin. On examination the overlying skin is bluish in color and there is a firm tender mass, which is nonfluctuant.

Treatment.—The pain and discomfort can be relieved by the moist heat of hot baths or compresses. An incision under local anesthetic will enucleate the dark blue clot and give immediate and dramatic relief.

Internal Hemorrhoids

Internal hemorrhoids consist of the enlargement of the internal hemorrhoidal venous plexuses, the main sites being at 3, 7, and 11 o'clock. The hemorrhoidal plexus is one of the main connections between the portal and systemic circulation, the others being the lower end of the esophagus, around the umbilicus, and between the renal and lumbar veins. Patients are predisposed to hemorrhoids by the inheritance of weak-walled veins and also by the absence of valves in the internal hemorrhoidal veins. The predisposition to hemorrhoids is aggravated by an increase in intra-abdominal pressure from straining at stool, constipation, pregnancy, and pelvic tumors. Hemorrhoids may also occur in portal hypertension.

Symptoms.—By far the commonest symptom is bleeding, usually at the time of defecation. The patient may also complain of prolapse, that is, the piles protrude and may have to be replaced manually. Discharge and irritation may accompany hemorrhoids, while pain is only associated with the complication of prolapse or thrombosis. They may occur at any time from adolescence onward. On examination the bluish bulging mucosa is readily recognized in the three primary positions, although it may vary in size. The examiner must be careful to distinguish between prolapsing internal hemorrhoids and prolapse of the rectum. This can be done easily, by asking the patient to strain. If a complete ring of mucosa appears outside the anal margin, prolapse of the rectum is obvious.

For convenience in description, first degree hemorrhoids are those that bleed but do not prolapse. Second degree cases prolapse and return again with or without bleeding. Third degree piles prolapse and become irreducible.

Complications.—The commonest complication is anemia, due to both the amount and duration of bleeding. The second complication is strangulation and thrombosis which occurs only with prolapsing hemorrhoids. Thrombosis may be followed by infection, accompanied by a sharp throbbing pain, or ulceration with a persistent discharge. Fortunately portal pyemia is now practically unknown.

Treatment.—This may be considered from three points of view. In mild cases and young individuals, *palliative treatment* may be all that is required. This consists of cold compresses combined with an analgesic ointment or suppositories. In those cases in which operative treatment is contraindicated, or in the milder cases, *injection therapy* may be carried out. The actual selection of cases is of fundamental importance in this treatment, the most suitable being first or second degree piles with no fibrosis and no external hemorrhoids. It is an unsuitable method for prolapsed third degree hemorrhoids, for fibrosis of internal piles, or for the compound external-internal variety. Injection therapy is carried out with a 5 ml Luer-Lok syringe and a long needle with a shoulder less than $\frac{1}{2}$ " from the tip. Three milliliters of 5% phenol and 5% menthol in almond oil are injected into the submucosa

near the base of the internal hemorrhoid, injecting one at a time at weekly intervals.

Complications of this treatment are remarkably few, but abscess formation and sloughing are occasionally encountered. If the injection is placed too low, there will be considerable pain from the phenol solution in contact with the anal sensory nerves.

Operative treatment is indicated in second and third degree hemorrhoids. It is contraindicated in pregnancy, in the presence of infection or gangrene, and in such general conditions as portal hypertension. A sigmoidoscopic examination is performed to exclude any other local organic cause. The hemorrhoids are dissected with a small flap of skin, demonstrating the subcutaneous external sphincter, and leaving a bridge of normal mucosa between the hemorrhoids. The base is ligated by transfixion, the bleeding points are carefully tied, and an absorbable hemostatic agent may be used as a pack. Early ambulation, hot baths, and mineral oil by mouth help toward a comfortable convalescence. Digital dilatation may be necessary to avoid a stricture. Postoperative pain may be prevented by injecting a local anesthetic in oil into the area at the time of operation.

Postoperative Complications.—Retention of urine is common, particularly with the use of spinal anesthesia. Secondary hemorrhage occurs occasionally, but careful technique will minimize this complication. Stricture formation may result if too much tissue is removed at the primary operation. This may often be prevented by repeated dilatations in the early postoperative period. Incontinence may occur as a result of damage to the external sphincter by excessive stretching or section or by the removal of too much mucosa, with consequent loss of sensation.

PROLAPSE OF THE RECTUM

Prolapse of the rectum is divided into two types: partial, consisting of the mucous membrane only, and complete, involving the entire thickness of the rectal wall. Partial prolapse usually occurs at the extremes of age. In children, it is due to a straight sacrum or to a lack of fat in the hollow of the sacrum and the ischiorectal fossa. The precipitating causes are usually constipation, straining, or diarrhea. In

RECTAL PROLAPSE

FISSURE-IN-ANO

Plate 33.—Common Anorectal Lesions.

adults, partial prolapse is often associated with hemorrhoids and is always the result of straining efforts common with constipation or enlargement of the prostate. *Complete prolapse* is rare. It is more common in females, occurs in both stout and thin persons, and should be looked upon as a sliding hernia of the pouch of Douglas.

Symptomatology.—There is slight bleeding after straining and discomfort of a mild type. Complete prolapse may be caused at any time by straining. There is a mucous discharge, incontinence, and regulation of bowel habit is difficult, so that the patient usually has to wear some pad or support. On examination, inspection is of the greatest importance. A swab is held over the anus so that there will be no incontinence when the patient is asked to strain. The rectum sometimes protrudes as much as 18". Palpation reveals the loss of sphincter tone. There may be ulceration of the mucosa, and even strangulation of the protruding mass, leading to irreducibility and gangrene. The diagnosis is easy but may be missed unless the patient is asked to strain. It is important to see the full extent of the prolapse, to replace the bowel as soon as it comes out, and then to decide on the line of treatment.

Treatment in Children.—This is conservative. Formal attempts at bowel training, such as leaving the child straining on the toilet for prolonged periods, may precipitate or aggravate the condition. The child's health must be improved. The specific treatment is reduction of the prolapse and maintenance of the reduction by strapping the buttocks together. Bowel training must be postponed until the condition is cured. Surgical treatment is rarely indicated except for those children who have a non-functioning anal sphincter or a defect in the levator ani muscle sling.

Treatment in Adults.—In *partial* prolapse associated with hemorrhoids it is only necessary to do a hemorrhoidectomy. The injection of 5% phenol in almond oil into the submucosa is helpful. In *complete* prolapse of the rectum, operation is advisable. Gabriel advocates the incision of the mucosa around the anal canal with amputation of the prolapsing portion of bowel through a *circular incision* and subsequent anastomosis. The second

method is that of Roscoe Graham: the abdomen is opened, and the floor of the pelvis is reconstructed; the rectum is then sutured to the pelvic floor, thus preventing prolapse from above.

Unfortunately both of these methods have a fairly high incidence of recurrence, because the underlying causes are still present. In order to reduce the recurrence rate, an addition to the method of Gabriel is advisable, namely, suturing the levatores ani to form a tighter sling.

CRYPTITIS

The small crypts behind the valves of Ball and between the bases of the columns of Morgagni frequently collect infected material, and these inflamed pockets are responsible for anal spasm, pruritus, pain on defecation, and even frequent bowel movements. The treatment consists of hot sitz baths and dilatation of the sphincter. The crypts should be exposed by a blunt hook and the free edge cut to give adequate drainage. The infection not infrequently burrows under the mucosa, causing a submucosal abscess.

ANORECTAL ABSCESS

Infection may be localized under the mucosa of the rectum or of the anus, as described under cryptitis, or the infection may be outside the muscular layer, either above or below the levator ani. Cases in which the infection is above are usually due to diverticulitis or ulcerative colitis, while those below originate in the ischio-rectal fossa. These abscesses and their situation are extremely important in themselves, but they become more so when considered from the point of view of their complications, of which the main one is *fistula-in-ano*.

The commonest type of anorectal abscess is the *perianal abscess* which may arise from the crypts, hair follicles, or sweat glands, associated with pruritus or systemic infection. The patient complains of pain on defecation, which is persistent and steady, and gradually increases in intensity until he cannot sit, stand, walk, or lie down without pain. The examination is difficult because the sphincter is in spasm and the induration is frequently masked. Examination under an anesthetic is necessary to deter-

mine the exact site of the abscess, and incision and adequate drainage should be carried out in order to prevent tracking of the abscess and fistula formation.

SUBMUCOUS ABSCESS

The mildest form of anorectal abscess is a submucous collection of pus, usually on the lateral wall of the rectum. It is often caused by abrasions but may follow thrombosis, injection of hemorrhoids, or cryptitis.

Treatment.—These abscesses may rupture by themselves into the rectum or anal canal; otherwise, they should be incised and drained and the edges cut to saucerize the area.

ISCHIORECTAL ABSCESS

The loose cellular tissue of the ischiorectal fossa may become infected from the rectum or skin, or infection may be brought there by the blood stream. The abscess may communicate with the rectum between the superficial and deep sphincters. It is very slow in development, with gradually increasing discomfort, deep throbbing pain, malaise, and a temperature up to 103° F. There are fullness and tenderness on examination, both externally and by rectum.

Treatment.—Under anesthesia an antero-posterior incision is made if the abscess is near the surface. If deep, a T-shaped incision is required, the edges are removed to saucerize the wound, and the cavity is packed. Postoperative sitz baths are instituted twice daily, and the wound is allowed to granulate.

PELVIRECTAL ABSCESS

Pelvirectal abscess is the rarest variety and involves the space above the levator ani. Infection usually arises from inside the pelvis. It may rupture into the rectum or through the levator ani. These patients have pelvic pain or discomfort, malaise, fever, and a marked leukocytosis.

Treatment.—The abscess should be drained through the ischiorectal fossa. It should be treated early in order to prevent complications, particularly high fistula-in-ano.

FISTULA-IN-ANO

Fistula-in-ano invariably results from a rectal abscess which burrows its way to the surface, producing a chronic granulating track. The track passes between the anal canal and the skin. Fistula-in-ano may be complete or incomplete. The complete variety has a fistulous connection between the skin and rectal lumen; there may be intermittent leakage of pus or feces. The incomplete form discharges either into the lumen of the bowel or through the perianal skin.

Etiology.—It is a disease of adult life, commoner in males. The infection may begin as an abscess in the submucosa and burrow its way to the surface as an ischiorectal abscess or, more rarely, from diverticulitis or ulcerative colitis.

Classification of Fistula-in-Ano.—

1 *Submucosal and subcutaneous fistulas.* These occur in about 15% of cases.

2 *Low anal fistulas.* Here, the track may be demonstrated by means of a probe passed from the skin to the anal canal, deep to the subcutaneous external sphincter. These make up about 75% of fistulas.

3 *High anorectal fistulas.* These usually begin from an ischiorectal abscess which has drained into the rectum as well as externally. They comprise about 10% of cases.

Diagnosis.—

Inspection.—Near the anus there is a small pimple from which pus may be discharging. The anterior fistulas are usually single, while those posterior frequently have multiple openings and side tunnels.

Palpation.—On inserting the finger into the rectum and squeezing downward, pus may be extruded, and with the passage of a probe, the track may be outlined. Should one suspect a complicated fistula, the injection of radiopaque Lipiodol is of assistance in estimating the complexity in a given case.

The diagnosis of fistula-in-ano presents little difficulty. The important point is to establish the bacteriologic cause, whether the lesion is due to pyogenic organisms or to the tubercle bacillus or actinomycetes. In tuberculosis there is usually a history of pulmonary infection, and if this is suspected, the specimen must be examined bacteriologically and pathologically.

ing. Some patients may have a relaxed sphincter with a continual leak of mucus. Others have excoriation of the skin which is heaped up in folds, with small fissures or ulcers between the folds. This is a warm, moist area suitable for the growth of parasites and mycotic infection. Lastly, there are those of obscure origin due to allergy or even psychoneurosis.

The investigation of a case in which the patient complains of itchiness in the anal region demands a thorough history and general examination, as well as a careful local examination. It is advisable to look especially for crypts, excoriation of the skin, and any other local cause, as well as careful examination for fungi, etc. The treatment is directed toward the following.

1. Hygienic measures Sitz baths twice daily, dusting powder, clean, well-fitting underclothes and clean bed linen
2. Dietetic measures If diet is a suspected causative agent, various elimination procedures may be tried

3 Medical therapeutics Treatment of constipation by mild laxatives, such as liquid paraffin, and attention to nutrition

4 Surgical treatment is reserved for intractable cases and consists of careful preparation of the patient for 2-3 weeks before admission with local antiseptics such as methylene blue or potassium permanganate. The definitive operative therapy provides wide excision of the skin and all the redundant folds in either a butterfly shape or sunflower pattern. This cuts the cutaneous nerves and enables the denuded area to heal by granulation tissue and become smoothly epithelized

PROCTITIS

Proctitis is a comprehensive term, including all the types of inflammation of the mucosa of the rectum. Simple, catarrhal, nonspecific proctitis is a localized form of colitis. It may be due to vitamin deficiencies, endocrine dysfunction, allergy, vasomotor disturbances, or even psychologic causes

Nonspecific

Acute proctitis is an acute hyperemia of the rectal mucosa with edema, vasodilatation,

and even hemorrhage. There is a granular appearance of the mucosa, with small, pinpoint ulcers. Digital examination of the rectum reveals that the wall is thickened and the lumen narrowed. The proctoscope shows a red, granular mucosa, which bleeds easily. Bacteriologic culture may reveal streptococci, staphylococci, and hemolytic streptococci, as well as *Bacillus coli*.

Chronic proctitis is the more chronic form of the disease and may be either hypertrophic or atrophic.

Irradiation proctitis occurs after deep x-ray therapy to the pelvis or radium treatment for carcinoma of the cervix. It consists of a hypertrophic, swollen mucous membrane with excess of mucus, and it is usually accompanied by rather severe steady pain. General treatment consists of liquid paraffin for soft stool formation and cleansing enemas. In more severe cases, a colostomy may be necessary for the relief of the recurring hemorrhage or stenosis

Specific

Bacillary or amebic dysentery must be confirmed by the growth and recognition of the causative organism

Tuberculous proctitis is usually associated with an active pulmonary lesion and may be complicated by tuberculous anal fistulas

Gonococcal proctitis is an acute proctitis with hyperemia of the mucosa and thick creamy pus. It must be bacteriologically diagnosed

Syphilitic proctitis. A primary chancre in the rectum may occur and usually presents as a small ulcer

Venereal proctitis is a lymphogranuloma venereum which may appear as an abscess, a stricture, or a small ulcer.

Treatment.—The treatment has been greatly simplified since the introduction of antibiotics. General medical measures may be used, such as sitz baths, oil enemas, and soothing ointments. The nonabsorbable sulfonamides will usually control acute nonspecific proctitis, while penicillin is specific for gonorrheal and syphilitic proctitis. Tuberculous proctitis is much more difficult to treat, demanding both general and local care. Streptomycin or its kindred antibiotics are efficacious for lymphogranuloma venereum

INJURIES OF THE RECTUM

Injuries of the rectum are not very common in civilian practice but increase during war-time. They may be divided into two classes—operative and traumatic. Accidents to the rectum occur during operations on the urethra, prostate, vagina, or uterus. The sigmoidoscope or enema nozzles may perforate the rectum during examination. A surrounding cellulitis or peritonitis may result. Recognition of such injuries usually occurs at the time of the accident, and the opening into the rectum can then be repaired immediately.

Gunshot wounds of the pelvis may affect the intraperitoneal or extraperitoneal portion of the rectum.

In crush injuries of the pelvis, a spicule of bone may perforate the rectum.

Rectal perforation also occurs from swallowed foreign bodies or from those introduced from below. These range all the way from a swallowed bone that has lodged transversely in the anal canal to the infinite variety of objects inserted into the rectum by children and lunatics.

Treatment.—Any foreign body should be carefully removed, and the rectum should be examined to make certain that there has been no damage to the wall. An anesthetic is frequently necessary as otherwise the procedure is extremely painful. Should there be perforation of the wall, a defunctioning colostomy is necessary until healing has occurred, then the colostomy may be closed.

STRICTURE OF THE RECTUM

Congenital stricture is mentioned in the section on imperforate anus (see Chapter 30). Post-traumatic stricture may follow perforating wounds of the rectum, and postoperative stricture may occur after hemorrhoidectomy or low intestinal anastomosis. Irradiation proctitis may result in a stricture formation. Lymphogranuloma inguinale is another common cause of stricture formation. This is a venereal infection caused by a filtrable virus and can be diagnosed by the Frei antigen test. Local examination of the rectum reveals a definite fibrous stricture, which is usually long and tubular,

associated with perirectal inflammation. In all cases of stricture the patient complains of progressive difficulty of defecation, straining at stool, and ribbonlike stools.

Treatment.

1. *Dilatation* is done repeatedly using rectal bougies of graduated sizes.

2. *Operation.* Internal proctotomy consists of cutting the fibrous stricture in 3 or 6 places.

3. The patient may require a *colostomy*, usually on the left side. Many cases of benign stricture of the rectum may be prevented by the early use of antibiotics in the treatment of the specific cause.

4. The extensive stricture of lymphogranuloma inguinale may require an abdominoperineal resection.

BENIGN TUMORS OF THE RECTUM

The commonest tumor of the rectum is a benign adenoma. The connective tissue tumors such as lipoma, fibroma, myoma, lymphoma, and angioma are rare. An *adenoma* is a small swelling, usually about the size of a pea which later enlarges up to about 3 cm. in diameter. It may be sessile or pedunculated and may be the site of malignant changes. The usual symptomatology is bleeding, discharge, and occasionally constipation or diarrhea. In children, the adenomas which usually cause bleeding are single and after removal cause no further trouble. In adults, the adenomas vary in size, number, and situation, as well as in symptomatology. Diagnosis is confirmed by sigmoidoscopic examination, when the polyp may be seen. It can then be grasped by forceps and removed by either a snare or cautery. The only point that should be stressed is that if there is a hereditary influence or the papillomas are multiple, then it is wise to have a radiographic examination in order to be sure that they do not extend along the bowel. *Multiple polyposis* of the colon, no matter what the age, is definitely a premalignant condition, and treatment is total colectomy. (See Familial Polyposis.) *Anal warts* or multiple papillomas of the skin around the anus occur. Treatment consists of removal by scissors under local anesthesia. The radiating wounds are then packed with petrolatum gauze.

CARCINOMA OF THE RECTUM

Incidence.—Cancer of the rectum and lower sigmoid comprises approximately 7% of all malignant tumors of the body. Men are affected more commonly than women in the ratio of 3 to 2. While no age is exempt, the most common decade for the occurrence of this form of cancer is 50-60, although many cases have been reported under the age of 30 years.

Etiology.—Though the true etiology of cancer is as yet unknown, certain lesions may be considered premalignant in the rectum. This is particularly true with multiple or single polyps.

Pathology.—A carcinoma of the rectum, excluding that of the anal canal, is an adenocarcinoma. It is in its early stages a local disease which begins as a local change in the epithelium or as a malignant change in a pre-existing adenoma. Varieties of adenocarcinoma which have been described include medullary, scirrhous, mucoid, and papillomatous.

Of more importance is the microscopic grading of the neoplasms, as has been described by Broder, who has divided them into four groups according to the degree of differentiation of the cells and the number of mitoses. The more undifferentiated the cells, the more malignant the tumor.

Malignant lesions of the rectum spread by direct extension and venous and lymphatic channels. It has been pointed out by Dukes that carcinoma of the rectum extends by direct spread through the rectal wall, and that lymphatic spread does not take place until the growth has reached the extrarectal tissues. His classification divides them into A, B, and C groups. A cases are those in which the growth is limited to the bowel wall (15%); B cases have involvement of the extrarectal tissues (30%); and C cases are those with metastases in the lymphatic nodes. This latter group may be further subdivided into near (C_1) and more distant (C_2) node involvement. The intramural lymphatics cause a spread within the wall of the bowel but for only a short distance above or below the lesion.

Of much more importance are the extramural lymphatic channels. Three methods of

extension occur: (1) downward, (2) laterally along the levator ani muscles, (3) upward to the retrorectal nodes, and then along the superior hemorrhoidal and inferior mesenteric vessels toward the periaortic nodes.

Venous spread, while much more serious than lymphatic involvement, occurs in 20% of cases.

Symptoms.—Carcinoma of the rectum in its early stages gives symptoms which may be slight or even absent, and the lesion may occasionally be discovered on routine physical examination. However, the most frequently encountered symptoms are bleeding, alteration in bowel habits, and pain.

Blood in small amounts, accompanied, as a rule, by the passage of excessive mucus in the stool, is the most common complaint. The blood is bright red and may either be mixed with the stool or may be streaked on the surface. The actual total blood loss is small, and anemia is not as marked as with carcinoma of other parts of the colon.

Alteration in bowel habit may be the earliest symptom. This may take the form of constipation or diarrhea. Tenesmus may be a prominent feature.

Pain is a late symptom and denotes a far advanced malignancy.

It is obvious that none of these symptoms is diagnostic of rectal cancer, but their presence should direct one's attention to a thorough examination of the rectum and colon.

Treatment.—The diagnosis having been established by biopsy, choice of treatment will depend on the site and size of the tumor. The results of radiation therapy have been disappointing, so that the only treatment is surgical removal.

For the noninvasive carcinoma confined to the mucosa and for carcinoma-in-situ, particularly in a polyp in the rectum which is within reach of the proctoscope, local excision with regular follow-up examinations afterward is a safe treatment. Invasive carcinoma, no matter how small, must be treated by radical excision. Carcinomas situated above the peritoneal reflection are usually classified clinically as situated in the rectosigmoid. In these cases, if the patient is not too fat or the pelvis too

small, it is possible to do a resection with end-to-end anastomosis. When the growth is at the level of the peritoneal reflection and below, then it is wiser to perform the abdominoperineal resection of Miles with terminal colostomy. This operation has been modified by the use of the two team synchronized combined abdominoperineal operation. The advantage of this method is wider

Fig 348—Classical abdominoperineal resection of Miles, for growths of Stages A, B, and C₁ of the rectum below the peritoneal reflection. The stippled areas represent the extent of the resection for primary lesions indicated by the black dots.

excision, and more extensive growths can be removed because direct vision from above and below at the same time is possible. Some authors advocate a proctosigmoidectomy with preservation of the anal sphincter. This method is suitable for selected cases, groups A and B only, with the growth at least 3" above the anal margin, and where the architecture of the sigmoidal arteries permits adequate mobilization of the sigmoid down to the anus. For advanced cases there is considerable debate whether an abdominoperineal operation should be performed when metastases are present in the liver. However, if the local growth can be removed, the last days of the patient will be more comfortable. In obstructed cases the obstruction must be relieved by means of a proximal colostomy, followed at a later date by abdominoperineal resection.

CARCINOMA OF THE ANUS

Carcinoma of the anus is comparatively comprising about 4% of rectal malignancy. It is squamous cell in type and produces stenosis of the canal. The diagnosis is easy: cause of pain, early bleeding, and the presence of an ulcer with hard everted edges, not accessible to the examining finger, and not visualized.

Adenocarcinoma may spread downward the rectum. Basal cell carcinoma is extremely rare in this region. Malignant melanoma can be distinguished from a thrombosed hemorrhoid, which can be done by biopsy.

Treatment.—The treatment of choice is surgical excision. Removal of the inguinal lymph nodes is sometimes debated but seems a wise insurance. Radiation therapy cannot be relied upon to control spread of disease into the hollow of the sacrum.

Fig 349—Pilonidal cyst and sinus.

PILONIDAL SINUS (SACRO-COCYGEAL SINUS)

Pilonidal sinus is a sinus lined with stratified squamous epithelium which is situated along the midline in the region of the sacrococcygeal junction. When the sinus track becomes blocked, it may go on to cyst formation. It may contain hair and retained secretions,

inflammatory changes frequently occur. The sinus opening may be single or multiple.

It is thought to arise from faulty development in the medullary canal or failure of union of the median raphe in this region.

Clinical Features.—In childhood, this condition is asymptomatic and consists of one or more small dimples in the midline. Symptoms do not, as a rule, develop until young adult life and are due to infection in the sinus which intermittently closes, fills up, and discharges again. Occasionally infection may spread and break out, causing new sinus openings. This may be precipitated by trauma, such as falls on the buttocks. It is more common in males.

Treatment.—In the acute stage abscesses should be drained. During the quiescent period all diseased tissue should be excised. If the resected area is not too large, the skin edges should be approximated, care being taken to obliterate all the dead space. So-called recurrences are due to inadequate primary removal of the sinus track.

An alternate treatment consists of marsupialization of the sinus track.

Chapter 28

Female Genital Tract

George A. Simpson, M.D., and William R. Foote, M.D.

Gynecology is defined as the study of the diseases of women, and in practice the gynecologist's efforts are centered on the diagnosis and treatment of diseases of the female reproductive organs. This does not free him from considering the other systems of the patient which may create symptoms referable to the pelvis. Contrariwise, disease of the pelvic organs sometimes simulates very closely those of acute and chronic surgical conditions of the other systems.

The greater proportion of gynecologic practice is formed of patients for whom the treatment is medical. One must not lose perspective while reading this section which tends to place special emphasis on the disorders that do require surgical measures.

SURGICAL ANATOMY

The female reproductive system has been differentiated into the lower and the upper genital tracts, and for our purpose the *lower genital tract* includes the vulva, vestibule, vagina, and the vaginal portion of the cervix, the *upper genital tract* comprises the supravaginal portion of the cervix, the body of the uterus, the fallopian tubes, and the ovaries, including the supporting structures of each division.

The lower genital tract may be inspected and palpated in its entirety so that localized lesions are ordinarily diagnosed by these simple means, with bacterial studies or tissue biopsy being used where indicated.

The upper genital tract is contained in the pelvic cavity, with the bladder anterior and the rectum posterior. While there are no superficial anatomic landmarks to aid one, these organs are usually readily palpated through the vaginal fornices or the rectum. With the other hand on the lower abdominal wall for counterpressure, it becomes only a matter of experience before the student becomes adept at diagnosis. There are pitfalls, of course, and these will be mentioned subsequently.

There are three anatomic features of significance: (1) As the *nerve supply* of the pelvic organs is incompletely understood, referred pain from pelvic disease is not definitive. There are apparently afferent pain tracts from the pelvic organs other than the presacral nerve, this fact, together with the multiplicity of the presacral nerve fibers sometimes present, suggests that presacral neurectomy will only give relief of pelvic pain in very carefully selected patients. (2) There is direct continuity between the vaginal orifice and the pelvic peritoneal cavity. (3) The pelvic peritoneum of the pouch of Douglas extends down to the upper fifth of the posterior wall of the vagina. In this area collections of pus, blood, endometriosis deposits, and metastases of malignant disease tend to accumulate. The pouch of Douglas can be drained by incising the posterior fornix (posterior colpotomy), and it is at this point that the culdoscope is inserted to obtain a direct view of the pelvic organs in selected cases.

GYNECOLOGIC HISTORY

When the patient visits the doctor, she has the history of her present complaint on the tip of her tongue, and it is usually wise to hear this in her own words before a more formal type of history is obtained.

The date of her last menstrual period is a useful starting point, and the information as to whether it came at the expected date and was normal in all respects is elicited. A more detailed menstrual history is then developed, and it is ascertained if there is irregularity, excessive loss, menstrual pain, intermenstrual spotting, painful intercourse, or abnormal vaginal discharge. Bladder and bowel habits and the presence or absence of abdominal pain are all ascertained as well as possible without too many leading questions. The history of all previous pregnancies, illnesses, and operations is important. These are often recalled vaguely, due in part to the paucity of detail given the patient by the doctor.

CLINICAL EXAMINATION

The abdominal examination is completely described in Chapter 32

The *pelvic examination* should be methodic and, with constant repetition which results from making it a routine part of the physical examination, the student is soon able to appreciate and detect the presence of abnormal findings

The patient, having emptied her bladder, is placed in the lithotomy position, with the hips well to the edge of the table. With good illumination, the external genitalia are inspected and then a speculum is introduced into the vagina and the cervix exposed. Smears for cytology are taken at this time with the Ayre spatula. The inspection of the cervix being completed, the vaginal walls are examined as the speculum is slowly withdrawn. A specimen of vaginal discharge is taken at this time for hanging-drop examination. With the gloved fingers lubricated, the urethra and the glands of Bartholin are gently palpated. Then, with the fingers depressing the perineum, the patient is asked to strain. This act usually exaggerates the relaxation and protrusion of the vaginal walls and causes descent

of the uterus if vault prolapse is present. Two fingers are then more deeply inserted into the vagina; the bimanual examination enables the cervix to be palpated and the position, size, and mobility of the uterus are ascertained. The internal fingers then deviate to the right and left fornices in an effort to outline the appendages. Normal appendages are not usually felt unless the abdominal wall is very thin and well relaxed. The posterior fornix is more easily examined by a rectovaginal technique which is ordinarily more disturbing to the patient than a vaginal examination. A simple rectal examination, however, will sometimes be as useful and less uncomfortable. In virgins, the latter is the only one that can be done unless the hymen is dilatable.

Fig. 350—Bimanual pelvic examination

Sometimes if the examination in the lithotomy position has been inconclusive, it is advisable to place the patient in the Sims' (left lateral) position and with a Sims' speculum repeat the procedure. If the patient is young or bashful this method may prove to be more acceptable, and it is the position of choice if the patient has to be examined in bed.

While the patient dresses, the examiner records the pelvic findings, correlates them with the history, and so arrives at a tentative diagnosis and the appropriate treatment.

On occasion a pelvic examination under an anesthetic is advisable, and this is usually combined with definitive treatment. Such examination should be routine before any laparotomy.

Uterine Anomalies

When the 2 müllerian ducts remain separate in their entire course, *uterus didelphys* results; 2 uteri, 2 cervixes, and 2 vaginae with a single tube and ovary attached to each uterus are found. The *uterus bicornis* with one cervix and vagina, the *uterus with a rudimentary horn*, and the *uterus with a septum* restricted to the body of the uterus are other varieties.

Diagnosis.—The diagnosis of these anomalies is not usually made until they are disclosed by routine hysterosalpingography performed in the investigation of infertility, or a dilatation and curettage are performed for an abortion. When pregnancy occurs and progresses to the third trimester, obstetric complications are common.

Treatment.—This is only indicated and satisfactory for minor anomalies.

PELVIC INJURIES AND DISPLACEMENTS

Vulvar Injuries

The larger proportion of these are noted during delivery, but others are caused by direct force to the vulva as the result of a fall or kick. In the first instance a hematoma forms, and this, if it remains small, usually subsides spontaneously; if the bleeding continues into the soft tissues, the hematoma becomes very large and pain may be severe. Soon the thin mucous membrane of the lower vagina is eroded, and disturbing venous bleeding occurs. In such serious injuries, the patient must be treated for shock and, as soon as practical, anesthetized and the hematoma evacuated. The tissue distortion is usually so marked that no single bleeding point is apparent, but the bleeding can be controlled by packing both the cavity of the hematoma and vagina and then applying firm vulvar pressure. A retention catheter is usually inserted.

A puncture type injury may involve deeper pelvic structures with but little apparent external injury.

Vaginal Injuries

A laceration of the hymen at coitus causes slight bleeding which stops spontaneously.

Rarely, the hemorrhage continues and it is necessary to suture the bleeding point.

In recent years potassium permanganate crystals have been inserted high in the vault of the vagina in an effort to produce a criminal abortion. The copious bleeding, which was believed to be uterine in origin, resulted from a burn. On speculum examination the cervix is found closed and intact, and the ulcerated burn lesion is apparent. Remaining crystals must be washed out with saline solution and a firm vaginal pack inserted to control the bleeding. Sutures are often necessary.

Vaginal Fistula

Vesicovaginal fistulas are a result of operative or obstetric injury, pelvic neoplasm, or radium burn. The incidence which follows obstetric trauma is less than formerly; immediate injuries are usually successfully repaired at the time and those due to bruising and ischemia have largely been prevented by improved obstetric practice. *Fistulas due to radium therapy are not as common with modern techniques and are usually a sign of persistent neoplasm.*

Vesicovaginal fistulas cause urinary incontinence which is complete unless the fistula is small. The drainage is noted within 10 days of the pelvic surgery or the removal of a retention catheter if one had been used. The site of the fistula is found by injecting methylene blue into the bladder and observing the leak by direct inspection. The Sims' position and the use of a Sims' speculum give very adequate exposure for this test. Sometimes cystoscopic examination is needed to localize the fistula and is required before any repair.

A small fistula may heal spontaneously, but most will require surgical closure after local cellulitis and infection have been controlled. The fistulas due to malignant invasion or radiation burns are particularly difficult to repair.

Rectovaginal fistulas may develop after breakdown or infection in a third degree perineal tear, after trauma during a rectocele repair, as a result of pelvic abscess drainage either spontaneous or surgical, or as a result of malignant invasion or radiation of malignant pelvic growths. Passage of gas and liquid bowel content through the vagina is the usual

symptom. Direct observation usually discloses the level of the fistula, and this may be verified by probing and proctoscopic examination.

A small fistula may heal spontaneously, but most will require surgical repair after proper sterilization of the bowel. Sometimes in an older patient with pelvic malignancy or radiation burn, a colostomy will give adequate relief.

Displacements of the Uterus

When one does a bimanual pelvic examination the position of the uterus is usually described as being anteflexed and anteverted. *Anteflexion* refers to the manner in which the body of the uterus is flexed anteriorly on the cervix, *anteversion* means that the uterus as a whole has a tilt which carries the body of the uterus anterior to the axis of the pelvis. This position of the uterus means that when a woman stands erect the uterus lies almost in a horizontal plane and at an angle of almost 90 degrees to the axis of the vagina. In about 20% of women, however, the uterus is in a position of retroflexion and retroversion without any reason and with no apparent ill effect. *Retroflexion* means that the body of the uterus is flexed posteriorly on the cervix; *retroversion* means that the uterus as a whole is tilted so that the body of the uterus lies posterior to the axis of the pelvis to a greater or lesser degree. Sometimes one finds on examination that the uterus is anteflexed, but it seems to fit into the curve of the sacrum; in this position the uterus is said to be *retroposed*. A rectovaginal examination is useful if the position of the uterus is not readily apparent.

A uterus that is retroflexed and retroverted but freely mobile rarely causes symptoms. Most gynecologists have had the experience of replacing and supporting a retroflexed and retroverted uterus with a pessary in an infertile female and then conception has occurred. Infertility may be an indication for surgical replacement, but the patients for this operation must be very carefully selected. In others who suffer from backache and dyspareunia with retroversion, a trial period with a pessary which gives complete relief would warrant a surgical suspension.

A uterus that is fixed in the position of retroflexion and retroversion usually has a pathologic cause. There may be chronic pelvic inflammatory disease with adhesions, endometriosis of the pelvis, enlargement of the uterus due to subinvolution, or fibromyomas. The tubes and ovaries as well are often fixed in the pouch of Douglas. The symptoms of backache, lower abdominal discomfort, leukorrhea and menorrhagia with dyspareunia and infertility may be present. The treatment in these patients must be that of the primary disease.

Does retroversion of a pregnant uterus predispose to abortion? Not ordinarily, but it is wise to caution the patient to refrain from intercourse until spontaneous correction occurs, and the knee-chest exercises may be prescribed even though their value is questioned by some.

Prolapse of the Vagina and Uterus

Prolapse of the uterus and a relaxation of the vaginal walls refer to the descent of the uterus and the protrusion of the vaginal walls which result from relaxation or tearing of the structures that support them.

Supports.—The pelvic floor is formed largely by the 2 levatores ani muscles and their fascial coverings which form a sling supporting the pelvic organs. The urethra, vagina, and rectum pass through the segment that is formed by the fusion of the 2 pubococcygeus muscles. These 2 muscles are attached to the posterior surfaces of the pubic rami and pass downward and backward to be inserted in the raphe between the rectum and the coccyx as well as to its tip. The fibers in relation to the rectum serve to support it. More anteriorly, the most medial fibers of each muscle give support by fusing with the urethral and vaginal walls, and they decussate between the vagina and rectum. These decussating fibers are the ones subjected to the greatest stretching and tearing during childbirth or by any condition that greatly increases the intra-abdominal pressure.

The levatores ani fuse with the vagina at the level of its middle and lower thirds and with the rectum at the level where it angles sharply backward and becomes the anal canal.

The urethra and vagina receive supplementary support below the pelvic floor from the urogenital diaphragm with its fascia and muscles, the insertions of which fuse with fibers from the levatores ani and the sphincter ani to form the *perineal body*.

The vault of the vagina and the cervix are well above the pelvic floor but still receive considerable support from it. However, their main support is supplied by the strong ligamentous-like tissues which lie superior to the fascia covering the upper surface of the levator ani muscles. These ligaments are called the *pubovesical ligaments* which extend anteriorly, the *uterosacral ligaments* which extend posteriorly and outline the pouch of Douglas and the *cardinal ligaments* which are the broadest and strongest and extend fanwise on either side to the lateral walls of the pelvis. The real strength of the supporting structures described above probably lies in the manner in which the fascial planes are so closely attached and fused together.

The round and broad ligaments play but a small role as supporting structures of the uterus.

A cystocele is a relaxation of the anterior vaginal wall, so that the bladder prolapses and the anterior vaginal wall protrudes. If the urethral support is stretched as well, a urethrocele is present.

A rectocele is a relaxation of the posterior vaginal wall which allows the rectum and posterior vaginal wall to protrude. When an enterocele is present, the relaxation of the tissues of the posterior fornix of the vagina is so marked that the upper part of the posterior vaginal wall with the peritoneum of the pouch of Douglas prolapses to the vulva. Coils of small intestine are often present in this hernial sac.

Prolapse of the uterus is of three degrees: first degree, the cervix descends in the vagina, second degree, the cervix presents at the vulva with straining; third degree, the cervix protrudes outside the vagina. *Complete procidentia* signifies that the uterus and vaginal walls are protruding below the vulva.

Elongation of the cervix may occur with no relaxation of the vaginal walls or vault prolapse.

These various conditions usually are present in combinations, and an over-all title, *sacro-pubic hernia*, is sometimes applied.

It is apparent from the above definitions that the patient will most commonly complain of a bulge in the region of the vulva and that this is aggravated by long standing, heavy lifting, or coughing. Lower abdominal discomfort and backache are often present, but bladder symptoms such as frequency and stress incontinence may be the most troublesome. With complete procidentia the bulk of the structures and the bleeding caused by friction on the mucous membranes distress and alarm the patient. It must be remembered that considerable relaxation of the vaginal walls may be present yet the patient is quite free of symptoms. However, as years pass, protrusion becomes more marked and symptoms develop which require treatment. Thus prolapse of a degree which causes symptoms is seen more commonly in the menopausal age group. At that time the relaxation and descent due to lacerations occurring during childbirth are accentuated by the atrophy and weakening of the pelvic supports, and symptoms become more apparent. Other predisposing factors are chronic cough, constipation, or chronic debility. Spina bifida and large ovarian cysts are rare causes.

Diagnosis.—The diagnosis of relaxations and prolapse is ordinarily not difficult and becomes apparent when the patient is asked to strain with the examining fingers depressing the perineum. A complete pelvic examination and smears of the cervix for cytology should be made. Urinary infection is often present, and in complete prolapse, ureteric obstruction may have caused upper tract renal infection and nitrogen retention. Before and after meal blood sugar tests should be done as a routine, since senile diabetes is more common in the patient with sacropubic hernia than in the population at large.

Treatment.—Treatment of prolapse may be conservative or surgical. During the child-bearing age, the pelvic support is strengthened by improving the health of the patient and instructing her in abdominal and pelvic floor muscle exercises. Insertion of a pessary to improve the position and support of the sub

involved uterus may be advisable. If repair is necessary in this age group, some authorities advise tubal ligation as well. If this is not done, subsequent deliveries may either progress normally, using a wide episiotomy, or cesarean section may be indicated. In the older patient a pessary will give temporary relief, but surgical treatment is ordinarily preferable.

The type of operation depends upon the degree of relaxation and prolapse, the presence of chronic cervicitis and hypertrophy of the cervix, associated uterine enlargement, or abnormal bleeding. Repair of the cystocele and rectocele may be all that is required, but if there is any degree of vault prolapse and uterine descent, one should perform the Manchester type operation which consists of amputation of the cervix, shortening of the cardinal ligaments, and repair of the anterior and posterior walls. If abnormal bleeding is a complaint then a vaginal hysterectomy with anterior and posterior repair is necessary. The LeFort operation (partial obliteration of the vagina by apposing the vaginal walls) is being used more rarely as gynecologic surgery and anesthetic procedures improve.

PAIN DUE TO PELVIC DISEASE

Acute pain of pelvic origin may at first be described by the patient as being worse in one or the other lower quadrant, but commonly it becomes diffuse over the whole lower abdomen. Chronic pain of pelvic origin, too, is usually diffuse, but the patient is often very indefinite about its severity and location, and she is disturbed mostly by the persistence of the discomfort.

The pain tolerance of the individual is sometimes difficult to assess, and this difficulty is increased because pelvic pain may be present to a disabling degree with very little evidence of pelvic disease. Conversely, a rather large pelvic mass may be present without causing symptoms. Interest has recently been revived in the clinical syndrome caused by chronic pelvic congestion. In this, lower abdominal pain, backache, and fatigue are the most characteristic symptoms, and the degree of tenderness is quite out of keeping with the pelvic findings. To assess the emotional factor in this type of pelvic pain is indeed difficult, but it

is very vital that this be considered if needless surgery is to be prevented.

The relation of the pain to the menses is important. If there is a history of delayed, abnormal, or missed periods, the pain is commonly caused by a complication of pregnancy, e.g., ectopic pregnancy. Midcycle discomfort may be due to ovulation, and pelvic inflammatory disease usually flares up in the post-menstrual phase.

Intense, acute, lower abdominal pain is associated with acute salpingo-oophoritis, ectopic pregnancy with rupture, torsion of the pedicle of an ovarian cyst, or degeneration of a fibromyoma. Except in the presence of continued internal hemorrhage, there is no marked immediate deterioration in the patient's condition and it may, in fact, gradually improve. This is unlike the course of an acute appendicitis, a ruptured viscus, or a spreading peritonitis.

Colicky pain suggests dysmenorrhea, a threatened or inevitable abortion, tubal abortion, or the presence of a large uterine polyp. Vaginal bleeding is almost always present with any of these conditions and serves to exclude lesions of the gastrointestinal or genitourinary tract, such as constipation, intestinal obstruction, or uterine calculi.

Dull lower abdominal pain may be caused by the pressure of pelvic tumors, and in this instance the discomfort is eased by change in posture. If the tumor is malignant, metastases and local infiltration will cause persistent pain.

Pain in the back in women is commonly caused by conditions other than pelvic disease, e.g., pyelitis. Backache, if due to gynecologic conditions, is usually in the lumbar or sacral areas. Sacropubic hernia or prolapse of the uterus causes this type of backache, with an associated vague discomfort in both groins. With other pelvic disease, backache is a late symptom and the condition is obvious on bimanual examination. Chronic cervicitis with a minimal parametritis may cause this persistent low back pain. Uncomplicated retroversion of a normal, mobile uterus seldom produces symptoms.

Pelvic pain of an acute character requires immediate diagnosis, and the treatment must be instituted, be it medical or surgical. Chronic

pelvic pain without very apparent pelvic disease must be observed over a period of time until the correct diagnosis is made. Often there will be an emotional state present or a disease of another system (gastrointestinal, genitourinary, or skeletal), and the need for gynecologic surgery is thus contraindicated. The forceful opinion of a consultant is an invaluable aid in treating these problem patients.

ACUTE PELVIC INFLAMMATORY DISEASE

Acute Salpingo-oophoritis

Pelvic inflammatory disease is predominantly due to an ascending infection, and the cervical canal is the barrier serving to protect the upper genital tract. A menstrual period opens this pathway to upper tract infection, e.g., gonorrhea, but an abortion, delivery, and instrumentation such as a dilatation and curettage are important predisposing factors. Pelvic tuberculosis is not an ascending infection (the exception) since the pelvic organs are infected by a blood-borne organism from a primary focus elsewhere in the body. Once the uterine cavity is invaded, a transient endometritis results and rarely a pyometra develops. The spread from the uterine cavity may be by continuity along the fallopian tubes, e.g., gonorrhea, or the infection may be carried into the pelvic tissues via the lymphatics or blood vessels, e.g., a placental site infection after an abortion. The causative organisms are the aerobic and anaerobic streptococci, the staphylococci, and the *Escherichia coli* groups *Clostridium perfringens* (Welch's bacillus) and pneumococcal infections are very rare.

With acute pelvic inflammatory disease, general malaise, pain in the lower abdomen of fairly intense degree, a temperature of 101° F or more, and a rapid pulse develop. Nausea or vomiting are not ordinarily present. On abdominal palpation the peritoneal reaction is apparent over the lower abdomen and at first may be more marked on one or the other side before becoming bilateral. On vaginal examination there may be evidence of a lower tract infection, e.g., urethritis or cervicitis, with a copious discharge, and specimen material is taken of this for bacteriologic studies and sensitivity tests. If there has been a recent

abortion or delivery, the discharge may be foul-smelling and sanious in character. On bimanual examination, movement of the cervix causes pain, and there is marked tenderness in both fornices. The uterus is partially fixed, but due to the abdominal splinting it is not often possible to delineate the size of the uterus or accurately outline the appendages. There is almost always bilateral involvement though one side may be more enlarged than the other. A rectovaginal examination is useful to verify the pelvic tissue thickening. The leukocyte count and the sedimentation rate are much increased.

Fig. 351.—Bimanual pelvic examination for pyosalpinx

An acute pelvic inflammatory disease may be present with uterine fibroids or be secondary to an infected ovarian cyst or pelvic appendicitis. In recent years the most fulminating cases have developed as a result of septic abortions.

It is most important to exclude an acute appendicitis. The onset of acute appendicitis is more typical and the symptoms of epigastric pain localizing in the right lower quadrant and an associated nausea and vomiting are characteristic. The temperature elevation and pulse rate increase are less marked. On abdominal palpation, the right lower quadrant splinting and a well-localized point of maximum tenderness about McBurney's point are present. On vaginal examination the lower tract is healthy.

and on bimanual examination the pelvic organs are normal and mobile. If there is tenderness present, it is in the right fornix and seems high up, out of the pelvis, unless the appendix is located in the pelvis or there is a marked peritoneal involvement. The leukocyte count and sedimentation rate are both increased and may not be of great help in the differential diagnosis.

An *ectopic pregnancy* with hemorrhage, complications arising from an *ovarian cyst* or a *fibromyoma*, *acute pyelitis*, or *renal calculus* must be carefully eliminated from the final diagnosis.

Prognosis.—The prognosis of uncomplicated pelvic inflammatory disease is good, and improvement is apparent within 4-5 days after treatment has begun. Chronic changes may persist even though the pelvic examination seems essentially normal, and these will be discussed later. If improvement is not noted, then a mixed bacterial infection is usually present and progression of the disease to pyosalpinx, pelvic abscess, generalized peritonitis, or septicemia must be suspected.

Treatment.—Treatment of acute pelvic inflammatory disease is nonsurgical and consists of bed rest, maintenance of fluid balance, with light diet if tolerated, and codeine for pain. Heat therapy may be applied to the lower abdomen, though some patients prefer an icebag. After the initial pelvic examination an enema may be given if required. Too frequent examinations, vaginal douches, or other pelvic manipulations are best avoided in the acute phase. Antibiotic therapy is started immediately and adequate doses of penicillin or the broad-spectrum antibiotics may be used. Laparotomy is indicated if the presence of an acute appendicitis or an infected ovarian cyst cannot be excluded.

Pelvic Peritonitis and Cellulitis

These cannot be differentiated since both are present in varying degrees. In the latter the inflammatory reaction is most evident in the broad ligaments and cellular tissues of the pelvis. The conditions develop more commonly after the evacuation of an infected abortion or after minor gynecologic operations performed in the presence of a lower tract infection which

seemed benign. Rarely, an exacerbation occurs as an isolated incident years after a previous attack.

Symptoms and Signs.—The early symptoms and signs are those described above, but improvement does not occur. The general malaise, a sustained fever, and a rapid pulse persist, and the abdominal pain becomes more marked. On examination one is able to palpate a diffuse tender mass arising asymmetrically from the pelvis, and this is formed by adhesions between the omentum, bowel, and pelvic organs. On bimanual examination there is marked tenderness, the cervix is fixed, and the pelvis is filled from side to side with a boardlike induration. This is the plaster-of-Paris pelvis of earlier writers. The induration may spread around the rectum in such a way as to suggest a malignant rectal lesion. The acute illness is prolonged, and abscess formation may result.

Pelvic Abscess

This is a late and uncommon complication of acute pelvic inflammatory disease, it may also arise as a complication of a ruptured appendix or an acute diverticulitis. There is by now a mixed infection present.

The patient appears more toxic and ill, the temperature remains high, and the leukocyte count and sedimentation rate increase. The pelvic pain is more marked and constant, and bowel pressure symptoms such as diarrhea may develop. On abdominal palpation there is usually some distention due to paralytic ileus, and the abdominal mass arising from the pelvis is more tender to palpation. Vaginal examination verifies the fact that the induration previously noted is more marked and the posterior fornix is bulging down below the cervix which is pushed well forward or to one side by the pelvic mass. Digital pressure on the mass causes marked pain, and sometimes fluctuation is noted. If the abscess is confined to a tubo-ovarian mass it will be less easily delineated because it will be higher in the pelvis and more to one side.

Treatment.—The treatment of these seriously ill patients is medical. The fluid and electrolyte balance must be carefully maintained, especially if gastric suction is necessary. Adequate doses of sedatives, blood trans-

fusions, and large doses of the suitable antibiotic drugs are given. A combination of sulfa drugs and antibiotics may be more efficacious. When abscess formation is apparent, a posterior colpotomy is performed, the sacculations are broken down gently with the examining finger, and a large drain is left in situ. If there is evidence that the abscess is pointing toward the peritoneal cavity, it must be drained through the abdominal wall. Sometimes an extraperitoneal approach is preferable, but in other cases the peritoneal cavity must be opened. The abscess is usually well walled off, and the pelvic structures are so disorganized that nothing more than drainage of the abscess is possible. *Paralytic ileus*, *generalized peritonitis*, and *fistula formation* may result if too much is attempted, while if drainage is inadequate the abscess will reform and the illness will be prolonged. Once the acute stage is past, further surgery to remove residual masses is better deferred for several months when the pelvic findings are reviewed.

Diverticulitis with rupture simulates pelvic inflammatory disease very closely. It occurs in an older age group, and the diagnosis may not be possible until investigations are completed after the subsidence of the acute symptoms.

CHRONIC PELVIC INFLAMMATORY DISEASE

This is the end result of the acute process and therefore the history is most important in making the diagnosis. It is said that gonorrheal salpingo-oophoritis is a self-limiting disease and leaves little residual damage, this may be true of a single episode of infection which is recognized and treated early. However, superimposed mixed infections or primary infection with other organisms is not uncommon and results in chronic tubo-ovarian disease. The fallopian tubes are chiefly involved. This may vary from an endosalpingitis with obliteration of tubal patency and a perisalpingitis with a few filmy peritoneal adhesions to the formation of a pyosalpinx or hydrosalpinx with marked peritoneal reaction and adhesions. These affect the tubes, ovaries, uterus, omentum, and the small and large bowel. The involvement is always bilateral, though one side may feel to be more grossly affected.

Chronic lower abdominal pain of a diffuse, aching character is the most common symptom, and this is especially apparent in relation to the menses, which may become more profuse and painful. There may be an associated lumbar backache. A vaginal discharge due to the chronic cervicitis is present, and intercourse is painful. Due to the tubal changes, infertility is a common complaint. An acute or subacute exacerbation may occur. There is little or no systemic reaction, though the patient is uncomfortable because of the chronic pain. On examination there is little but diffuse tenderness over the lower abdomen to be found. Pelvic examination shows evidence of a catarrhal cervicitis, and on bimanual examination the uterus is normal in size and partially fixed in retroversion and the body of the uterus is acutely tender to pressure. The appendages are palpably enlarged, tender, and bound down, their outlines often ill-defined, and, on recto-vaginal examination, they may be fixed in the pouch of Douglas. It is amazing how extensive the pelvic involvement is found to be at operation when bimanual examination only suggested moderate inflammatory changes.

Pelvic endometriosis, an organized pelvic hematocoele formed by a tubal abortion, or a diverticulitis of the bowel will simulate the pelvic findings of chronic pelvic inflammatory disease. Fibromyoma of the uterus or ovarian tumors may coexist and cause difficulty in diagnosis.

Treatment.—This is essentially conservative and should continue over a considerable period of time. The general health is improved by adequate diet and rest, and any anemia must be treated. Bowel habits must be regulated, especially around menstruation time. Daily copious warm douches may be comforting, but pelvic dathermy treatments are usually more efficacious. Mild analgesics are prescribed for the pain. Chemotherapy and antibiotic treatment have little effect on these lesions.

Ordinarily the patient can be reassured that the disease is not serious and will gradually improve with treatment. In a small percentage, the pain remains to an incapacitating degree, and the pelvic masses persist. Subacute or acute relapses further demoralize the patient. Surgical treatment is then advisable after consultation. The diseased organs, including the uterus,

should be removed, saving as much healthy ovarian tissue as possible, though this may not be practical. Pelvic peritonitis may develop in the immediate postoperative phase, and it is therefore wise to give adequate antibiotic therapy both before and after operation.

The possible extent of the operation must always be explained to the patient and to her husband, especially if she is in the below-40 age group.

Tuberculosis of the Pelvic Organs

This is usually a blood-borne infection from a primary site elsewhere in the body, and this focus of infection may have been quiescent for a number of years. In fact, it is unusual to have an active primary focus to aid in the diagnosis. Rarely, there may be a generalized tuberculous peritonitis with subsequent spread to the pelvic organs. In either instance the fallopian tubes are first affected, pelvic peritonitis develops, and the ovaries and body of the uterus are involved in the inflammatory reaction. The adhesions may be dense and extensive. The endometrium is almost always affected.

It is clear that a careful history must be taken to elicit the presence of tuberculosis in the immediate family or, more usual, of tuberculous disease in the patient herself.

Pelvic tuberculosis so closely simulates pelvic disease due to the gonococcus or the non-specific infection that follows abortion or delivery, that it is not commonly diagnosed as a separate entity. The patient is therefore treated conservatively with rest and penicillin or sulfonamides which characteristically do not improve the condition. It is only when the chronicity of the disease begins to undermine the general health and to incapacitate so that she is unable to earn her living that further investigation is deemed advisable. Endometrial biopsy or a curettage, if done in the late premenstrual phase, often enables the diagnosis of tuberculous endometritis on pathologic study of the tissue. Smears and culture of the endometrium are less reliable, but a portion of the endometrium should be used for guinea pig inoculation to make the diagnosis positive. If tuberculosis of the endometrium is present and there are also bilateral tubal masses, pelvic

tuberculosis may be diagnosed. If an acute exacerbation occurs it is usually precipitated by a mixed bacterial infection. In the older age group uterine fibroids may obscure the diagnosis.

Treatment.—The treatment in such a case should be conservative, with a sanitarium regime if possible. The use of para-aminosalicylic acid, isoniazid, and streptomycin is of great value, but masses already present do not often resolve completely. If permanent benefit is not obtained with the above regime, then laparotomy is advised.

On opening the peritoneal cavity the findings may be so like that of any pelvic inflammatory disease that the diagnosis is still not suspected. In another patient there are the typical retort-shaped tubal masses with tubercles studded over the pelvic tissues. In both of these situations bilateral salpingectomy and total hysterectomy should be done, leaving any ovarian tissue that is sufficiently healthy. With a more marked involvement, all structures of the pelvis, including small and large bowel, are densely adherent. In the rare case there is a widespread tuberculous peritonitis with ascites. It would be advisable in the latter two instances to close the abdomen after taking tissue for study, institute sanitarium and specific drug therapy, and then review the question of a second operation months later.

Prognosis.—This is good for most patients. A postoperative course of drug therapy should be given and convalescence in a sanitarium advised, since there is a remote chance of the primary focus becoming active again or a miliary type of tuberculosis developing.

BLEEDING

The average menarche begins between the ages 12-14 years and the outside limits of the normal are 10-16 years. Wider variations may be indicative of tumors of the ovary, adrenal, or pituitary, or of certain endocrinopathies. While the menstrual interval is usually 28-30 days, there are wide individual variations. The normal duration of flow is about 5 days, and the menstrual discharge is usually dark and free of clots. With more profuse flow the blood is brighter and may be clotted.

Associated symptoms are dysmenorrhea, heaviness in the pelvis, backache, headache, nausea and vomiting, change in the bowel habits, and emotional upset.

Changes in the patient's menstrual history are of utmost significance in diagnosing gynecologic disease. Excessive bleeding and prolongation of the period without alteration of the menstrual cycle is designated *menorrhagia*, too frequent cycles constitute *polymenorrhea*, and vaginal bleeding between periods is known as *metrorrhagia*.

Abnormal bleeding usually flows from the uterine cavity, but it also may be associated with lesions of other parts of the genital tract or even with general systemic disease and endocrine disturbances.

The local causes may be tabulated:

- 1 Vulvar bleeding
 - a Lacerations
 - b Rupture of varicose veins
 - c Vulvitis or ulceration
 - d Urethral caruncle or carcinoma
 - e Carcinoma
- 2 Vaginal bleeding
 - a Lacerations
 - b Ulceration
 - c Vaginitis
 - d Carcinoma
- 3 Cervix
 - a Erosion and ectropion
 - b Cervicitis
 - c Polyps
 - d Carcinoma and sarcoma
- 4 Uterine bleeding
 - a. Trauma, perforation or rupture
 - b Infections
 - (1) Endometritis, acute or chronic
 - (2) Metritis and parametritis
 - (3) Chronic subinvolution
 - c. Neoplasms
 - Benign
 - (1) Endometrial polyp
 - (2) Fibromyoma
 - (3) Adenomyoma
 - Malignant
 - (1) Carcinoma
 - (2) Sarcoma
 - d Conditions associated with pregnancy
 - (1) Abortion
 - (2) Extrauterine pregnancy
 - (3) Ante partum and post partum hemorrhage
 - (4) Hydatidiform mole
 - (5) Chorionepithelioma
 - e Functional uterine bleeding
- 5 Fallopian tubes
 - a Pregnancy
 - b Salpingo-oophoritis
 - c Carcinoma

Abnormal bleeding tends to have varied significance, depending upon the patient's age. In the first few days of life vaginal bleeding, often associated with engorged breasts, is due to excessive maternal estrogenic hormone and is without importance.

In childhood, bleeding may be caused by a precocious menarche, vaginal tumor, or foreign body, and rarely by a feminizing tumor of the ovary or malignant disease of the cervix.

In adolescence, menorrhagia can occur at the onset without organic lesion. This is functional in origin and is often associated with anovulatory cycles. It may alternate with periods of amenorrhea. Ovarian growths and malignancy of the uterus at this age are fortunately rare.

During the reproductive period (15th to the 45th year) abnormal bleeding is most commonly caused by disturbances of pregnancy, pelvic inflammatory disease, polyps, fibroids, and malignant growths.

At the menopause, changes in the cycle are common, but menometrorrhagia or postcoital spotting must be studied with the greatest care to rule out benign or malignant disease of the genital tract. Postmenopausal bleeding is most significant and is usually due to *uterine malignancy*, foreign bodies, senile vaginitis, or cervical polyps and rarely to a feminizing tumor of the ovary. It may follow estrogen therapy, and the patient must always be asked if such a hormone has been taken.

Abortions

Abortion is defined as the termination of pregnancy prior to fetal viability, which is the 28th week of pregnancy. The incidence of abortion is higher than is generally believed, perhaps 15-20% or more, and the greatest cause by far is the abnormal ovum itself, faultily developed, improperly fertilized, or abnormally implanted.

Abortions are classified as threatened or inevitable and, if the latter, as complete or incomplete, noninfected or infected.

Threatened Abortion.—Abortion is most often threatened in the first 3 months of pregnancy, before the placenta is fully formed. It is characterized by vaginal bleeding or spotting and lower abdominal pain similar to

menstrual cramps, although the cervix remains closed. Differential diagnosis includes ectopic gestation, cervical erosion, polyps, and cervical carcinoma. Treatment should be rest in bed, sedatives, and analgesics. Vitamin E, estrogens, and progesterone are popular medications but are of doubtful value. A urine pregnancy test may be useful, ■ pelvic examination should be avoided at the onset of symptoms for fear of further disturbing the pregnancy. If the symptoms persist or progress, this examination must be done.

Inevitable Abortion.—If the pain and bleeding increase and examination shows that the cervical canal is dilating, the abortion has become inevitable. The internal cervical os as ■ sphincter will never close until the contents of the uterine cavity have been expelled.

Complete Abortion.—If the products of conception are expelled, cessation of pain and subsidence of bleeding follow. If one is absolutely sure the abortion is complete, no operation is required. The patient is kept in bed a few days and given oxytocics to aid in uterine involution.

Incomplete Abortion, Noninfected.—In this case the products of conception have not been completely passed. Dilatation of the cervix, gentle curettage, and evacuation with ovum forceps are necessary to remove the remaining tissue. Excessive loss of blood must be replaced by transfusions at the time of curettage. It may be necessary to control any uterine hemorrhage after curettage by packing and oxytocics.

Incomplete Abortion, Infected.—Septic abortion is caused by the infection of retained products of conception. This ■ commonly introduced by foreign bodies or solutions used in an attempt to terminate pregnancy. Uterine and tubo-ovarian infection, pelvic peritonitis, thrombophlebitis, pyemia, or septicemia may result. It is best to treat first the infection with antibiotics, transfusions, and bed rest. When the temperature has been normal for 48-72 hours, the uterine contents are gently evacuated. The only exception is when the infected incomplete abortion is associated with uncontrollable hemorrhage; immediate evacuation of the uterus is then imperative.

Missed Abortion.—The uterus does not expel the perished ovum. First there may be

vague contractions and little bleeding, but these subside. The diagnosis is made by later noting involution of the breasts, failure of the uterus to enlarge, and the negative pregnancy tests. If, in time, the uterus does not expel its contents it may be stimulated to do so by large doses of estrogenic hormone, followed by Pitocin. If ineffective, dilatation of the cervix and evacuation of the uterine cavity are indicated.

Hydatidiform Mole.—This condition occurs about once in 2,500 pregnancies. Whether it is degenerative or neoplastic in origin is unknown. There is proliferation of the trophoblastic covering of the villi, edema of the stroma, scantiness of the villous blood vessels, and ordinarily no trace of the fetus. Because of the vesicular change of the villi, the mole has the appearance of a bunch of grapes.

The chief symptom is continued bleeding in the 3rd or 4th month of pregnancy, sometimes with passage of characteristic villous tissue. The uterus is often larger than normal for the period of amenorrhea and there is an absence of fetal movements, although the subjective signs of pregnancy are present and the urine pregnancy tests are strongly positive.

Hormonal studies are important. There is an overproduction of chorionic gonadotropic hormone which is found in great quantities in the urine, blood, and spinal fluid. If the urine shows more than 200,000 mouse units of the hormone, the diagnosis usually is justified. Treatment is evacuation of the uterus and blood transfusions as required. A careful follow-up is necessary because of the danger of subsequent chorionepithelioma. The incidence of malignant change is 1-2%. Urinary studies must be continued for 12-24 months, even if the tests become negative. Persistent high chorionic gonadotropic hormone indicates retention of actively functioning trophoblastic tissue, and a second curettage ■ indicated. If the test continues positive (and there is not a superimposed new pregnancy), especially with bleeding and subinvolution of the uterus, hysterectomy must be performed. An x-ray of the lungs should be taken to exclude metastatic chorionepithelioma.

Chorionepithelioma.—This highly malignant disease, although rare, may develop after

hydatidiform mole, full-term delivery, or abortion. Vaginal bleeding is the chief symptom, but the disease may first be detected by metastases in the lower genital tract or in a distant organ such as the lung. Cough and hemoptysis may develop, and x-ray of the chest will show the typical metastatic invasion of the lung. Hormonal studies are invaluable, but the final diagnosis must be made by study of the tissue secured by curettage. There is destruction of the myometrium by invading trophoblastic tissue, which is disorderly in pattern and malignant in cellular appearance. Treatment is total hysterectomy and bilateral salpingo-oophorectomy followed by irradiation therapy since chorionepithelioma is radiosensitive. Metastatic growths may disappear either because of the latter treatment or because the primary uterine tumor has been removed, but the prognosis is poor.

Fig 332—Sites and relative frequency of ectopic pregnancy

Ectopic Pregnancy

This occurs when the fertilized ovum implants itself outside the cavity of the uterus. The most common site for this to occur is in one of the fallopian tubes, a *tubal pregnancy*. Implantation and development of the fertilized ovum progress. The endometrium of the uterus responds to the hormonal stimulation of the tubal pregnancy and amenorrhea results. Other symptoms and signs of pregnancy may or may not be present. Before long the erosion and distention of the tubal wall result in rupture of the tube or the expulsion of the pregnancy through the fimbriated os of the tube. Either

of these events causes pain and intraperitoneal hemorrhage. When the hormonal balance is upset by interference with the implantation site, intrauterine bleeding occurs. This is apparent to the patient as vaginal spotting, which later may become moderate bleeding.

Tubal pregnancy with rupture and diffuse intraperitoneal bleeding creates the classic syndrome of amenorrhea of 5-6 weeks' duration, sudden, severe, stablike lower abdominal pain, and collapse, with all the signs of internal hemorrhage. On examination the patient's pallor is marked and she is in a state of collapse. The lower abdomen is tender, usually soft, perhaps distended; on pelvic examination there is almost always slight vaginal bleeding and exquisite pain on manipulation of the vault of the vagina or cervix. The cervix is soft and closed, and the uterus, if palpable, is enlarged slightly.

With tubal abortion and slower hemorrhage, the clinical picture is less spectacular. The diagnosis is not commonly made on the first examination. There is an indefinite history of a missed period, then crampy intermittent lower abdominal pain develops, and unilateral abdominal tenderness is present. Vaginal bleeding occurs and often persists, though the symptoms and signs become less marked. Often the patient is treated for pelvic inflammatory disease or an incomplete abortion until, later, further internal hemorrhage occurs despite bed rest. Then there is a recurrence of the colicky pain, an increasing anemia develops, and reflex shoulder pain may be present due to diaphragmatic irritation. On pelvic examination an indefinite tender mass, a *pelvic hematocoele*, is felt in the pouch of Douglas or in relation to the appendages.

Differential Diagnosis.—Aids to the differential diagnosis of ectopic pregnancy are a pregnancy test, an examination under an anesthetic, curettage, and posterior colpotomy. The pregnancy test, if negative, does not exclude an ectopic pregnancy.

This is differentiated from *acute appendicitis* by the sudden onset, the presence of uterine bleeding, and the evidence of internal hemorrhage with the associated vaginal findings.

Acute pelvic inflammatory disease usually produces quite a different course of events. However, chronic salpingo-oophoritis is fre-

quently the initial diagnosis when a tubal abortion is actually present and either may be superimposed on the other. The history of a missed period, the crampy pain, the vaginal bleeding, and a tender pelvic mass which increases in size while the patient is under observation are most characteristic of a tubal pregnancy. If a tubal pregnancy is suspected, the pelvic examination should be gently done, because brisk intraperitoneal hemorrhage may be started. This is particularly important if the patient is at home where shock treatment is not available.

An incomplete abortion creates more profuse bleeding and less pain. On examination the uterus is usually larger and there is more marked cervical dilatation. The products of conception are expelled, sooner or later, through the cervix.

An ovarian tumor with torsion of the pedicle causes sudden, severe abdominal pain and local peritonitis which may simulate an acute appendicitis or intraperitoneal hemorrhage. Ordinarily the cyst is of moderate size but enlarges rapidly after torsion and intracystic hemorrhage. The patient may be in a state of collapse with a subnormal temperature. If the tenderness of the abdomen excludes proper abdominal palpation, it is sometimes possible to feel the rounded, tender mass in the pelvis. Examination under anesthesia will verify the diagnosis. Rupture or infection of an ovarian cyst is less common and produces peritonitis. Diagnosis may be difficult. The treatment is prompt laparotomy and removal of the tumor.

Rupture of a graafian follicle at ovulation time at midcycle may be painful (mittelschmerz) if minor intraperitoneal hemorrhage occurs; this bleeding is usually minimal, the acute episode passes, and while regional tenderness may persist, the progressive signs which suggest an ectopic pregnancy with tubal rupture or acute appendicitis do not develop.

Treatment.—In any ectopic pregnancy the treatment is surgical after preparations are made for the treatment of the blood loss and shock. The affected tube is removed, leaving the ovary if this is practical.

Uterine Polyps

Polyps arise from the cervix or body of the uterus. *Cervical polyps* are mucous in type and

are small. They arise in the cervical canal. Symptoms are mucous discharge, irregular spotting, or postcoital bleeding. *Intrauterine polyps* arise from the endometrium or from a submucous fibroid; rarely are they placental in origin. They cause menorrhagia and intermenstrual spotting.

Speculum examination will show a cherry-like cervical polyp or a uterine polyp protruding through the cervical os.

Although small cervical polyps may be destroyed by the cautery, it is usually wiser to hospitalize the patient. Under anesthesia the cervix is dilated, the polyp removed by torsion from its origin, and the uterine cavity carefully curetted for associated disease or other polyps. The tissue can then be histologically examined for possible malignant changes.

Fig. 333.—Positions of uterine myomas

Fibromyomas (Fibroids)

These are benign new growths of the uterus and are usually multiple. They may be of various sizes and may arise in varying parts of the uterus, thus causing asymmetric enlargement. The rate of growth in the absence of complications is slow, and a very large proportion are asymptomatic. The tumors are most commonly diagnosed in patients 35-45 years of age, during which period symptoms tend to develop. Fibroids, as they enlarge, are prone to secondary degeneration due to impaired blood supply. Hyaline, cystic, and fatty changes may develop. During pregnancy, red degeneration may occur and cause much pain. After the menopause, simple atrophy is usual, but sometimes a calcified

fibroid may be seen. Sarcomatous degeneration occurs rarely, 1% or less.

Symptoms.—These are profuse prolonged menstrual bleeding with secondary anemia, discomfort due to pressure, and a relative infertility. As the size increases, abdominal swelling may be noted, and a feeling of heaviness in the lower abdomen may be described. Marked epigastric discomfort is a rather unusual and misleading symptom. Acute pain arises if the fibroid undergoes degeneration or torsion. These complications cause a rapid increase in the size of the uterus, but an associated pregnancy must be excluded.

Fig. 354.—Bimanual examination for fibroid uterus

On lower abdominal palpation a firm asymmetric mass, which is usually not particularly mobile, may be demonstrable. On bimanual examination the hard mass is felt arising from the pelvis, it is continuous with the cervix and is defined as the asymmetrically enlarged body of the uterus. The mobility is more apparent on bimanual examination unless there is fixation due to adhesions from an associated pelvic inflammatory disease or endometriosis or there is impaction of the fibroid in the pelvis. The fornices are clear unless the fibroid extends into the broad ligament. No fetal parts or movements are apparent. The mass is dull to percussion, and on auscultation a souffle may be present. The pregnancy test is negative, and the fibroids grow more slowly than a pregnant uterus.

In certain cases a uterogram to visualize the interior of the uterus may be an aid in diagnosis. The cavity is usually asymmetric if fibromyomas are present.

Treatment.—Completely asymptomatic fibroids may be left alone, but the patient should have a routine bimanual examination every 6 months. A small fibroid with irregular bleeding warrants a diagnostic dilatation and curettage. The treatment of fibroids, which are causing secondary anemia due to hemorrhage or discomfort due to the size and pressure, is surgical. Myomectomy may be successful in a limited number of younger patients who wish to have children. Hysterectomy is usually the operation of choice, and the ovaries should be conserved if there is no ovarian disease.

Carcinoma of the endometrium may be associated with fibroids. For this reason all uteri removed must be opened at once and carefully examined by an assistant. If gross inspection is suggestive of carcinoma of the endometrium or sarcoma of the fibroid, then the ovaries should be removed.

Functional Uterine Bleeding

In functional uterine bleeding, the normal cycle may be maintained with the bleeding prolonged or profuse, the cycle quickened or even doubled, and intermenstrual bleeding may occur. This may alternate with periods of amenorrhea. The mechanism is not clearly understood and is probably due to a variety of causes, such as imbalance between the two ovarian hormones, estrogen and progesterone, failure of the spiral arterioles to contract, or abnormal uterine muscle response. An important feature is that the abnormal bleeding must have persisted over several cycles.

In some cases there is failure of ovulation and persistence of unruptured graafian follicles with resultant hyperplasia of the endometrium (metropathia hemorrhagica). In other cases the endometrium is found to be atrophic, and in others progestational, indicating ovulation. Behind this is an imperfect knowledge of the effect of the gonadotropic hormones of the pituitary gland upon the ovaries. There may be an emotional or stress factor in this type of bleeding.

Treatment.—This will vary according to the age of the patient, the severity of the bleeding and the need to preserve reproductive function. In the young girl ovulation may not occur and she may have irregular cycles with

increased bleeding. These will be spontaneously regulated in time. Rectal examination will most often reveal normally developing pelvic organs. Care is taken to control anemia. Hormone therapy, other than thyroid, is used in carefully selected cases. Examination under anesthetic and curettage are only occasionally required for persistent heavy bleeding.

During the active *childbearing period* functional bleeding may be a distressing problem. It is at this time that hormone therapy has its greatest value. It is important to emphasize that before it is used, organic lesions must be excluded by physical examination, diagnostic curettage, or endometrial biopsy.

The hormones used in treatment are as follows:

1. Estrogens, synthetic, e.g., diethylstilbestrol, and natural, e.g., Premarin or ethinyl estradiol. These may be given cyclically for several weeks and gradually withdrawn. The purpose is to raise the estrogen level in cases where bleeding is caused by such deficiency.

2. Progesterone, by subcutaneous, sublingual, or vaginal absorption. When bleeding is due to persistent proliferative endometrium, progesterone may bring about the secretory phase, with cessation of bleeding.

3. Combined estrogen and progesterone therapy. This is often effective, perhaps by re-establishing a normal balance between the pituitary gland, the ovary, and the endometrium.

4. Androgens, sublingually or intramuscularly. When administered in less than masculinizing doses they are helpful in controlling functional bleeding.

5. Thyroid extract. This is indicated where hypothyroidism exists.

6. Gonadotropic preparations.

If the bleeding cannot be controlled with hormones or by curettage, more radical treatment is necessary. With a patient in the late 30's hysterectomy may be advisable after a second opinion has been obtained.

Radiotherapy should be avoided if possible as its effect on the ovaries varies.

At the menopause the treatment is more exact. Again organic disease such as carcinoma or polyps must be excluded, and this diagnostic curettage may control the abnormal bleeding. Since a curettage is not always permanently

effective, total hysterectomy rather than repeated curettage is the treatment of choice. In surgically poor-risk patients, intrauterine radium or x-ray irradiation must be considered.

CARCINOMA OF THE UTERUS

Cervix

With the exception of the breast, the cervix is the most common site of cancer in women. It is at least 3 times as frequent as cancer of the uterine body, but together they make up 30% of all cases. Because the cervix is accessible for study and diagnosis, and because the cancer is frequent and grave, the examining doctor is offered an opportunity for early detection and a correspondingly high percentage of cures.

Predisposing factors are trauma and chronic irritation. Much has been written of the higher incidence of cervical cancer in females who have married early and borne many babies, as opposed to the much lower rate in virgins and nulliparae. However, the physician should concentrate on elimination of cervical irritation, infection, erosion, and on the detection of pre-invasive cancer when and if it occurs.

There are two types of cervical cancer; 95% arise from the squamous epithelium and 5% develop from the columnar epithelium of the endocervical glands, i.e., adenocarcinoma. In the early stages the cervix may look normal, especially if the cancer is confined to the cervical canal; there may be a vascular erosion that bleeds on touch or a granular area at the squamocolumnar junction. In the more advanced stages the cancer may form a crater-like ulcer or a cauliflower-like growth.

The microscopic appearance is that of cancer cells showing disparity in size and nuclei, excess mitosis, hyperchromatosis, and karyorrhexis, although in some the departure from normal differentiation is relatively slight. This must be coupled with an abnormal pattern or architecture so that the epithelial cells push through the basement membrane and invade the stroma.

Spread may be (1) direct to the vagina and uterine body, outward to the parametrium where it may involve the ureter, forward to the bladder, and backward along the uterosacral ligaments to the rectum; (2) by lym-

phatics, primarily to the paracervical node, obturator, hypogastric and external iliac nodes, and secondarily to the sacral, common iliac, inguinal, and aortic nodes, (3) by the blood stream to the liver, kidneys, lung, and bones, a late and rare occurrence.

Classification follows that of the League of Nations Health Organization.

Stage 0—Carcinoma-in-situ, also known as preinvasive carcinoma, or intraepithelial cancer

Stage I—Carcinoma confined to the cervix.

Stage II—Carcinoma with infiltration of the parametrium on one or both sides without involvement of the pelvic wall. Stage II vagina: The vagina is infiltrated in the upper two thirds only. Stage II corpus: The corpus uteri is infiltrated

Stage III—The cancerous infiltration of the parametrium has invaded the pelvic wall on one or both sides, or the lower third of the vagina is invaded, or isolated malignant nodules are felt on the pelvic wall.

Stage IV—The cancer involves the bladder as determined by cystoscopic examination or by the presence of vesicovaginal fistula; or the cancer involves the rectum, or has spread outside the true pelvis.

Carcinoma-in-situ has aroused much discussion. It may be defined as a complete replacement of the normal squamous epithelium by undifferentiated cells morphologically indistinguishable from cancer. However, there is no break in the basement membrane, although the cells may creep into the lumen of the glands. This condition, without recognizable signs or symptoms, may precede, or exist at the periphery of, invasive cancer of the cervix. Positive cervical smears occasionally will not be supported by the subsequent ring biopsy. Cases of carcinoma-in-situ under observation may become negative on cytologic study after biopsy.

Symptoms.—The first symptom is abnormal vaginal bleeding, usually intermenstrual spotting which occurs after intercourse, douching, or straining with defecation. This may be preceded by a yellow or brown watery discharge which becomes blood-stained and foul-smelling. Pain is a late symptom and suggests invasion of the tissues outside the cervix.

Pain may be only a pelvic discomfort or there may be low backache with radiation into the thighs. Bladder irritability and rectal discomfort indicate extension to those organs.

Diagnosis.—The onset of cervical cancer is insidious and the initial symptoms are trivial in character and comparatively late in appearance. Cervical cancer may be diagnosed and treated before any symptoms appear. This can only be achieved by thorough and periodic examination of the cervix and willingness of the patient to cooperate and to report the slightest symptoms. Vaginal spotting, discharge, and pain are not pathognomonic, but they do suggest a lesion, either cancer, erosion, inflammation, or polyp.

Pelvic examination and visualization of the cervix are necessary. If the clinical diagnosis is not apparent, a cervical smear is obtained with a spatula, and an aspiration smear of the uterine cavity is recommended. The smears are examined by a trained cytologist. When anaplastic cells are found, a ring biopsy at the squamocolumnar junction is taken for serial section examination. At the same time the cervix is dilated and fractional curettage of the endometrium and endocervix is performed.

The Schiller test, based on the fact that iodine will stain normal cervical cells a deep mahogany brown while cancer epithelium remains unstained, may be used to distinguish areas for biopsy. Unfortunately leukoplakia, traumatized mucosa, eversion, and erosions take the stain poorly and make the test less useful.

Biopsy with microscopic examination is the important diagnostic method.

Treatment.—

Carcinoma-In-Situ.—Preinvasive carcinoma occurs in younger women in whom sexual function and childbearing must be considered, and it may be permissible to use surgical conization of the cervix rather than hysterectomy, with prolonged postoperative follow-up. Where further reproduction is not desired a total hysterectomy is advisable, removing the cervical fascia and a wide cuff of the vagina. The ovaries may be conserved.

Carcinoma of the Cervix.—Treatment may be irradiation, surgery, or a combination of both. Controversy still exists. Irradiation ther-

apy can be used in any stage of cervical cancer and is particularly applicable to the poor-risk patient. The gamma rays of radium and deep x-rays are applied in a dosage to destroy the tumor cells in the cervix, parametrium, and pelvic lymph nodes with minimal damage to normal tissues. The technique varies, but in this center a modified Stockholm technique, a combination of radium followed by deep x-ray, is used. The radium is applied in the uterine cavity, around the cervix, and in the vagina in such a way as to radiate both locally and to the paracervical tissue and nodes. It is given in two doses of 3,000 mg /hours each, 10 days apart. This is followed by deep x-ray therapy through two anterior and two posterior ports to reach the lateral tissues of the pelvis. The total skin dose varies from 3,000-4,000 r to each field. Thus the total dose of x-ray in the average case is 3,500 r to the tumor area, given over a 7-week period.

Irradiation may cause nausea and vomiting, rectal and bladder irritation, or the flaring up of an old pelvic infection. Later reactions are fibrosis, vaginal atresia, proctitis, bladder ulceration, and vesicovaginal or rectovaginal fistulas.

Surgical treatment has been successfully performed for Stage I and early Stage II cancer in surgically fit women by use of the radical Wertheim hysterectomy and pelvic lymphadenectomy.

Two further indications for surgery are the detection of radioresistant cancer or recurrence after adequate irradiation. The surgery depends on the extent of the lesion and may be a radical hysterectomy with pelvic lymphadenectomy or pelvic exenteration, anterior, posterior, or complete. These have a high mortality, with extensive suffering and prolonged hospitalization and convalescence. When curative treatment has failed, the physician will have much to offer for the relief of pain with drugs or with resection of the spinothalamic tracts.

Corpus Uteri

Carcinoma of the body of the uterus is recognized more frequently today and the ratio to cervical carcinoma is about 1:3. It occurs later in life than cervical carcinoma, as a rule, and its

association with obesity, diabetes, relative infertility, abnormal menstrual cycles, and menopausal hyperplasia has been noted.

Carcinoma arises in the endometrium, from the epithelium, or from the glands. The adenomatous type is the most common and may be localized to a single area, or polypoid processes may project from an extensive area and fill the uterine cavity. The microscopic appearance is almost always glandular. There is a marked increase and disorderly arrangement of the acini, and the individual cells show varying degrees of immaturity and anaplasia.

Adeno-acanthoma is an interesting variant in which patches of squamous epithelium are found intermingled with adenocarcinomatous tissue.

Spread.—The carcinoma remains limited to the uterus much longer when occurring in the body than when arising in the cervix. It is restrained by the uterine musculature and proceeds only in the advanced stage by the lymphatics to the broad ligament, tubes, ovaries, and the lumbar chain of lymph nodes. Secondary growths can occur in the vagina by direct extension. Pyometra is a common complication of the advanced stage.

Symptoms.—Abnormal vaginal bleeding is the most frequent and important symptom. In the menstruating age, menorrhagia and metrorrhagia are common, and in the postmenopausal woman, spotting is suggestive. Abnormal discharge, at first watery, then brownish, bloody, or foul-smelling is significant. Pain is a late symptom.

Diagnosis.—Negative cervical and endometrial aspiration smears do not exclude endometrial cancer, and a diagnostic curettage is mandatory. In more than half the cases the bleeding will be due to benign hyperplasia, polyps, submucous myoma, unsuspected incomplete abortion, or senile endometritis.

The microscopic study of the curetted tissue will give the diagnosis in most cases. In some it is difficult, and pathologists may differ in their interpretation of hyperplasia and endometrial polyps.

Treatment.—Total hysterectomy, including removal of the cervical stroma and a wide cuff of the vagina, together with bilateral salpingo-oophorectomy is the most satisfactory treat-

erated blood (*chocolate cysts*). Endometriosis of the pelvic organs is the most common form; however, the small bowel, large bowel, and bladder may be involved, usually secondarily to the pelvic condition. More rarely, extra-pelvic tissues are involved.

Pelvic endometriosis may occur at any time during menstrual life. Diagnosis is difficult since the symptoms and signs are diverse and develop slowly. With *adenomyosis uteri*, the clinical diagnosis is rarely made. Menstrual pain and menorrhagia gradually develop in multiparae over 35 years. On bimanual examination the uterus is smooth and symmetrical but may be bulky and tender. The appendages seem normal. These findings do not warrant surgery at first, but continued ill health after curettage on one or more occasions indicates more radical treatment and a total hysterectomy is necessary.

With *external endometriosis*, chronic symptoms develop which are aggravated with the onset of each menstruation, and these increase in severity as the invasion spreads. There is present the symptom-complex of acquired and increasing menstrual pain, dyspareunia, and pelvic discomfort due to pressure. Menstrual irregularities may be present, and a suggestive feature is a prolonged period of infertility.

In the early stage, pelvic examination discloses nothing palpably abnormal, though thickening of the uterosacral ligaments may be noted. Later, the findings are almost indistinguishable from those of chronic pelvic inflammatory disease. There is, however, no history of fever or previous infection. As the involvement extends, the uterus becomes fixed in retroversion, and bilateral, tender, cystic ovarian masses are felt. The definite hard, irregular nodules in the rectovaginal septum are usually diagnostic. Rectal symptoms may be produced by this septal involvement.

The wall of the large bowel may be invaded by endometrial implants which cause dimpling due to fibrosis and later, stricture of the bowel lumen. Abdominal pain and constipation recur with the menses, and eventually partial obstruction may result. Neoplasm of the colon may be suspected, but the rectal mucosa is usually intact, and this serves as a diagnostic aid in excluding carcinoma of the

bowel. The bladder wall is not often sufficiently involved to cause characteristic cyclic symptoms and signs.

At operation minute purplish spots distributed over the pelvic peritoneum suggest the diagnosis, and there are marked cystlike formations (*chocolate cysts*) with gross dense adhesions involving the pelvic structures. The lines of cleavage of the adhesions are found with difficulty, and usually the endometrial cysts are ruptured, allowing varying amounts of chocolate-like material to soil the pelvic region. It is apparently innocuous but peritoneal cleansing should be as adequate as possible.

Treatment.—Treatment with hormones and continued observation may be effectual in young adults with menstrual pain and minimal pelvic findings. With greater involvement, surgery is advised, and the present trend in surgical treatment of pelvic endometriosis is to be as conservative as possible. The condition will regress if pregnancy occurs or if the ovaries are removed. In the younger age group (25–35 years), therefore, one removes only grossly disorganized structures, and, if practical, one leaves some ovarian tissue. The patient usually accepts the conservative operation in preference to spaying, even though a second operation or deep x-ray therapy may be necessary later. Suspension of the uterus and presacral neurectomy may be combined with conservative surgery, but each case must be carefully assessed. In the older group (35–45 years) the tissues are more likely to be extensively involved, and total hysterectomy and bilateral salpingo-oophorectomy may be necessary. If scarring of the rectovaginal septum is marked, this may be technically difficult, but as much of the cervix as possible is removed.

PELVIC TUMORS

Excluding the pregnant uterus at or near term, neglected fibromyomas, very large ovarian cysts, tuberculosis of the peritoneum, or malignant ovarian cysts with metastases and ascites, pelvic tumors do not cause generalized enlargement of the abdomen. Obesity, ascites, and phantom tumors should also be remembered. A full bladder or a loaded bowel is

easily excluded by catheterization and emptying the lower bowel with an enema.

At puberty, if a persistent vaginal septum be present, a lower abdominal tumor may be formed, and the menstrual fluid accumulates in the vagina (a hematocolpos) and the uterus (a hematometra).

Abdominal distention of a greater or lesser degree is a common complaint at the menopause. The distention comes and goes, and its very indefiniteness ordinarily indicates its minor importance.

A tumor localized to the lower abdomen may be uterine or ovarian in origin. Pregnancy, fibromyoma of the uterus and ovarian cysts are the most common conditions which may produce an abdominopelvic mass in the absence of marked pelvic infection. It must be remembered that pregnancy and a fibromyoma or pregnancy and an ovarian cyst may coexist.

The Pregnant Uterus

This is the most common pelvic tumor. The history of amenorrhea, associated with breast changes and the other symptoms and signs of pregnancy, should prevent errors of diagnosis. The pregnant uterus is ordinarily uniformly enlarged and is soft on bimanual palpation. A pregnancy test may be necessary. Otherwise one can postpone the diagnosis until another month has elapsed, and then the rapid, symmetric globoid enlargement due to the pregnancy will be apparent. Later, of course, fetal movements, fetal heart sounds, or x-ray demonstration of fetal bones gives the diagnosis absolutely. The physician must remember the value of auscultation of the tumor, an x-ray of the abdomen, and a pregnancy test.

Fibromyoma

(See previous section.)

Ovarian Tumors

These are predominantly cystic in character, but some are solid. They vary tremendously in size and contour, but the size does not always account for the symptoms nor is it a measure of the potential danger to the patient. Certain types tend to involve one ovary only, and if bilateral tumors are present, the possi-

bility of malignant changes are more likely. Some are remarkably mobile because of the long pedicle, while others are impacted and fixed in the pelvis. The former usually rise up into the general cavity, while the latter remain in the pelvis and distort the normal relations of the pelvic structures. The rate of growth is faster than that of a fibroid and is especially rapid if intracystic hemorrhage occurs.

TABLE 24
CLASSIFICATION OF OVARIAN TUMORS

1 Retention cysts of the ovary	
a Follicular cysts	
b Corpus luteum cysts	
2 Cystic and solid tumors	
Benign	Malignant
A Cystic	
Serous papilliferous cystadenoma	Papilliferous adenocarcinoma
Pseudomucinous cystadenoma	Pseudomucinous adenocarcinoma
Endometrioma	
Cystic teratoma (Dermoid cyst)	Epithelial element carcinoma
B Solid	
Fibroma	Teratoma
Granulosa cell tumor*	Sarcoma
Thecoma*	Granulosa cell tumor*
Arrhenoblastoma*	Thecoma*
	Arrhenoblastoma*
	Dysgerminoma
Brenner tumor	Brenner tumor
	Primary carcinoma
	Secondary carcinoma
	Bowel
	Stomach
	Uterus
	Breast

*Tumors that are functioning or that secrete sex hormones

Follicular cysts may be created by hypersecretion rather than by pure retention, but the end result is the same. The ovary involved is not greatly enlarged and usually contains more than one enlarged follicle. The other ovary may be involved as well. The ovaries are usually quite discrete, though there is often an associated chronic pelvic inflammatory disease, retroverted uterus, or uterine fibromyoma—all believed to be causative factors. There are no specific symptoms, though it is feasible that anovulatory cycles may result or a metrorrhagia develop. Simple puncture of the largest follicles is usually sufficient, but the presence of many small cysts may necessitate a wedge resection.

A corpus luteum cyst is a small cystic area in the ovary which may look like a hematoma. The whole ovary is seldom larger than a hen's egg, the surface over the cyst may be cratered but the ovary itself is smooth and discrete. Because of the hormonal imbalance caused by the persistent corpus luteum, a menstrual upset may be present. If a hydatidiform mole is present, both ovaries may be enlarged to a greater extent due to the existence of multilocular theca lutein cysts. *In any event, an ovary which contains only a follicular or corpus luteum cyst should not be sacrificed.*

Serous cystadenoma may be quite a minute cyst but usually is the size of a large grapefruit when the diagnosis is made. The surface is smooth, shiny, and whitish, and the remaining ovarian tissue is thinned out so as to be indistinguishable. A single ovary is generally affected, and the tumor is discrete and freely mobile. It is usually on a pedicle which renders it subject to torsion with resultant intracystic hemorrhage. The cyst, in the absence of hemorrhage, contains clear fluid and its lining may be quite smooth, *the simple type*, or it may be lined with many papillary growths, *the papilliferous type*. The tumor is usually asymptomatic until symptoms from pressure or torsion of the pedicle occur. The papilliferous cysts have a tendency to become malignant, and this is suggested by the presence of bilateral cysts with external papilliferous projections or the presence of ascites with papilliferous metastases throughout the peritoneal cavity. In any event the specimen must be opened and examined carefully in the operating room and the decision regarding malignancy made on the gross appearances.

Pseudomucinous cystadenoma is the most common ovarian tumor. The cyst is multilocular and varies in size from a small lesion to one that fills the entire peritoneal cavity. The locules give the cyst an irregular form and the contained material is sticky or mucinous, with a characteristic yellowish tinge. The other ovary is also involved in a considerable proportion of cases, but the tumor masses remain discrete and the tough outer wall usually persists intact. If rupture should occur, the mucinlike material may fill the entire pelvis or peritoneal cavity. *pseudomyxoma*

peritonei, but this is rare. There is a high incidence of malignancy which, however, may be restricted to one small loculated area. The borderline between the benign and malignant tumor is very difficult to distinguish even for the pathologist, and at operation the characteristic signs listed above are not often apparent. If adenocarcinoma is diagnosed on pathologic study, the remaining pelvic organs must be removed as soon as practical. Deep x-ray is an alternative therapy in selected cases.

Endometrioma (see endometriosis).

Cystic teratomas (dermoid cysts) are among the commoner ovarian tumors and are generally present in a younger age group than other cysts. The weight and size cause discomfort, the tumor usually being about the size of a large grapefruit. There is a long pedicle and one ovary is involved, though the other may be the site of a much smaller dermoid cyst. On inspection the mass is discrete with a smooth, dense, bluish-white surface free of any lobulation. On opening the cyst the presence of sebaceous material and hair confirms the diagnosis, and there is an ectodermal plate which includes skin, teeth, and cartilage. There is little danger of malignancy. The dermoid cyst can be dissected from the ovarian tissue if the latter is not too attenuated, but if the other ovary appears quite normal, the affected ovary is removed. Because of the young age of the patient the treatment is as conservative as possible.

Solid teratomas originate from tissues derived from all three primitive germ layers and occur in the younger age group. The tumor is unilateral, occurs rarely, and is highly malignant, so that the prognosis is poor.

Fibroma is a solid tumor which may involve only a small part of the ovary, or it may diffusely replace the ovarian tissue. The one ovary is involved, the tumor is smooth and solid, but, as in a fibroid, cystic changes may be present. The size is seldom greater than a large orange. An important clinical feature is that ascites and hydrothorax may be present with this benign tumor.

Sarcoma of the ovary is rare. Both ovaries may be affected, and again the tumor is solid, though cystic changes may be present.

Granulosa cell tumors and thecomas are solid ovarian tumors known as functioning

or feminizing tumors because they secrete estrogen and thus upset the normal hormonal balance. One ovary is usually affected; the smooth tumor remains small and its size rarely equals that of a grapefruit. When sectioned, small cystic areas may be present, and the granulosa tumors may show a yellowish tinge. The tumor can occur at any age and produces precocious puberty in the young child, irregular bleeding during the reproductive years, and uterine bleeding in the postmenopausal period. These symptoms, plus those due to pressure which may develop, bring the patient for advice. The tumors are potentially malignant. In the younger age group, only the affected ovary is removed, but in anyone over 40 years bilateral salpingo-oophorectomy and total hysterectomy should be performed in the presence of such a solid tumor.

Arrhenoblastoma is a rare ovarian tumor which develops during young adult life, and due to its secretion of androgen it is known as a functioning or masculinizing tumor. Secondary amenorrhea and breast atrophy occur, hirsutism develops, and the clitoris becomes hypertrophied. The ovarian tumor is usually unilateral, solid, and smooth. The symptoms and signs of masculinity regress after the tumor is removed. Again the tumor or tumors may be malignant, and the other ovary must be carefully inspected and even incised at the time of operation.

Brenner tumors are pathologic curiosities. The tumor is solid, remains small, and has no special clinical character.

Dysgerminoma is another pathologic curiosity. The tumor is solid and causes pelvic symptoms through pressure due to its size and weight. The clinical feature to be remembered is that it occurs in young adults and in children. It must be considered malignant.

Carcinoma of the Ovary.—From what has been said it is obvious that carcinoma of the ovary may develop in an apparently benign tumor, while in other cases the initial growth is malignant. The latter are particularly lethal since the neoplasms grow silently until metastases occur and give rise to symptoms of pressure, with vague gastrointestinal or abdominal distress. By the time ascites is present, both ovaries are commonly affected, though to a variable extent.

Secondary carcinoma of the ovary may be a metastatic spread from other pelvic organs such as the uterus or rectum, or it may be secondary to a distant focus such as the colon, stomach, or breast. It has become apparent in recent years that two primary lesions may occur in the same patient. The secondary involvement of the ovaries is almost always bilateral, and although the typical *Krukenburg tumor* is a solid type, other metastatic tumors may be cystic and show few malignant characteristics until pathologic study is made. If, on the other hand, there is a generalized carcinomatosis of the peritoneal cavity, it may be difficult to establish the primary source even at autopsy.

Fig 357.—Bimanual examination for ovarian cyst.

Symptoms and Signs Common to Ovarian Tumors.—The smaller tumors tend to be asymptomatic, but as the size increases, the patient complains of a feeling of heaviness or dull ache in the pelvis, with possibly bladder pressure symptoms. If the tumor arises out of the pelvis it usually is a midline tumor, and the swelling is sooner or later noted by the patient. Menstrual irregularities are not common (unless the tumor secretes hormones), but as pelvic congestion and disorganization of the ovary proceed, the menstrual loss may vary in quantity and interval.

On abdominal examination the swelling may be apparent. On palpation it is usually a smooth cystic midline tumor arising from the pelvis to a point at or below the umbilicus; it is dull to percussion and silent on auscultation. Ascites is rarely demonstrable with benign neoplasms but is common with malignant changes. On bimanual examination the cervix

and body of the uterus are felt to be quite separate from the mass arising out of the pelvis, but the bulk of the latter may displace the uterus back or to one side. With bilateral tumors the differentiation of the uterus is more complex. The mass almost always feels cystic, and this point plus the fact it is separate from the uterus differentiates it from a fibroid in most cases. Rectovaginal examination is important since in endometriosis or malignant metastases the pouch of Douglas is involved. An x-ray of the abdomen outlines the contour of the tumor, and the presence of teeth indicates a dermoid cyst.

Acute pain usually is caused by a *complication* such as torsion of the pedicle, intracystic hemorrhage, and rarely rupture or infection. These create all the symptoms and signs of an acute abdominal emergency.

The greater proportion of ovarian tumors is innocent in type, but malignant changes either primary or secondary are present in approximately 25% of such cases. Malignant tumors are more common in the older age groups. The symptoms are exaggerated, the pain is more marked, and on examination the debility of the patient, the ascites, the irregular abdominal masses, the fixation of the pelvic masses, and the secondary deposits in the pouch of Douglas are all suggestive.

Treatment.—The treatment of a well-defined ovarian tumor is surgical removal. Some of the smaller cysts may be observed for 2-3 months, and a small proportion will disappear only to recur later. In the menopausal age group, any ovarian tumor should be removed.

If the tumors are bilateral and apparently innocent, the larger cyst is removed while the smaller may be shelled out, leaving some ovarian tissue. It is difficult to define the presence of carcinomatous changes, and therefore all cysts should be opened and carefully examined in the theater after removal. If copious ascites is present and if the tumors are bilateral and papilliform projections are present on the exterior of the cyst, the pathologic report will bear out the clinical impression of malignancy. The uterus should be removed in these cases. In patients with cancer of the ovary with metastases, little can be accomplished, but

biopsy of the tumor should be done to aid in the diagnosis. If practical, the other abdominal organs should be examined for a primary source. The use of radioactive colloidal gold in the peritoneal cavity appears to control ascites and small metastatic seedlings in some cases. Deep x-ray therapy gives variable results with carcinoma of the ovary. The use of chemical derivative therapy appears to give promising palliative results.

VAGINAL DISCHARGE (LEUKORRHEA)

Since the vaginal mucosa lacks intrinsic lubricating glands, the lining of the vestibule and vagina is moistened by a vaginal transudate and also by secretions from Bartholin's glands and from glands of the cervix. The vagina is practically always nonsterile from a bacteriologic point of view, but the organism are nonpathogenic. The mucosa is thick and the cells rich in glycogen. The hydrogen ion concentration is regulated at a pH of approximately 3.5-4.5. Should this state of acidity be disturbed, the bacterial balance is altered and vaginitis results from the multiplication of pathogenic organisms. There is a normal variation of the vaginal pH in the child and again after the menopause. In both, the reaction is alkaline, pH 7-8, the mucosa is thin, and the cells have scanty glycogen. The resistance of the vagina to infection is lowered at these ages. General debility, diabetes, and pregnancy are other predisposing causes of vaginitis.

Leukorrhea is a symptom and denotes an abnormal vaginal discharge which is not blood stained. The exaggerated discharge may be mucoid, purulent, offensive, curdlike, or watery in character and, in the absence of a foul odor or vulvar irritation, may be tolerated by the individual. Modern cancer propaganda has served to make women conscious of such discharges. Leukorrhea is usually present with precancerous lesions of the cervix, and if routine smears for cytology are taken, unsuspected cancer is sometimes disclosed.

Mucoid Discharge

Mucoid discharge may be clear or milky and is ordinarily benign in origin. It is pro-

duced by stimulation of the cervical glands and is increased just before and after menstruation. Unless very profuse, no specific treatment is required, although any simple cervical erosion or laceration should receive treatment.

Purulent Discharge

This denotes the presence of pathogenic organisms, and while gonorrheal infections must always be kept in mind, the more common infections encountered in practice are due to *Trichomonas vaginalis*, *Monilia* (*Candida*) *albicans*, *Escherichia coli*, streptococci, or staphylococci, or any combination of these. The infections are most common through the childbearing period, and there is usually a cervicitis present with varying degrees of erosion and laceration. Other symptoms are foul odor, pruritus, and chafing of the vulvar area, with painful intercourse.

Trichomonas vaginitis is common during the reproductive period, and the causative organism is the *T. vaginalis*, a flagellated protozoa. The *T. vaginalis* is often found in the vagina without symptoms and thrives in a medium, pH 5.5-6. With overwhelming infection the patient is in continuous distress, and there is a sensation of burning on micturition. Examination of the worst cases reveals an excoriated vulva with the redness extending to the thighs. On gently inserting the speculum, a copious, frothy, greenish, foul-smelling discharge is observed. The inflamed vagina and cervix, when swabbed clear of discharge, have a peculiar strawberry appearance. The presence of motile *T. vaginalis* in great numbers on microscopic study of a smear diluted with normal saline confirms the diagnosis.

The treatment is restoration and maintenance of a high vaginal acidity to destroy the infecting organisms. The vagina is cleansed and one of the many proprietary medications insufflated or inserted. The patient continues the insertion of the suppositories night and morning as directed. This treatment is maintained throughout the whole cycle, and an occasional cleansing douche of vinegar solution may be used. Intercourse is temporarily prohibited. A cure is not to be assumed until several consecutive periods have passed with-

out relapse, which is most likely to occur in the postmenstrual phase. When the vaginitis is persistently recurrent, the husband's prostatic secretions should be examined as a possible source of infection.

Monilia (*Candida*) *albicans* vaginitis creates less discharge, although the pruritus is severe. The external irritation is more marked if the patient is pregnant or has diabetes mellitus. Moniliasis may occur at any age. On examination the typical vaginal findings are the whitish, curdlike plaques which are adherent to the vaginal wall and cervix. The inflammatory reaction is moderate, though the introitus is often reddened. The diagnosis is apparent on inspection but may be substantiated by demonstrating the mycelia and spores of the fungus in a smear diluted with normal saline. In an atypical vaginitis both *T. vaginalis* and *Monilia* may be present.

The treatment is careful vaginal toilet with a cleansing solution and then the application of a preparation such as gentian violet either in fresh 1% aqueous solution or as a gel. This may be repeated once or twice as required. Glycosuria should always be excluded, and if the condition persists, blood sugars should be estimated.

Mixed bacterial vaginitis results from staphylococcal, *E. coli*, or streptococcal infections, and its only characteristics are foul odor and persistence of the discharge. This type of infection seems more prone to develop in the young girl, nullipara, or postmenopausal woman. Smears and cultures will demonstrate the predominant bacteria, and if sensitivity tests are performed, the applicable antibiotic may be given. In other instances sulfonamide cream or antibiotic suppositories may be inserted. Recurrence often occurs after the antibiotics are discontinued; but if they are continued too long a troublesome monilia may be superimposed. If instillations are used, local allergic reactions may be very distressing. Normal saline or vinegar solutions may be used as cleansing douches.

If the discharge is very foul and profuse, the presence of advanced carcinoma or foreign body in the vagina may be suspected. In the postmenopausal patient, intermittent escape of foul-smelling purulent discharge may be caused by a pyometra.

Watery Discharge

Watery discharge, if continuous, may be due to a vesicovaginal fistula. If intermittent, it is possible that it arises from the cavity of the uterus or the fallopian tubes. In pregnancy, it may indicate escape of amniotic fluid in the last trimester.

Senile Vaginitis

This results from the marked atrophic changes due to deficiency of estrogen after the menopause. A mixed infection is present and is usually mild in character. The chief complaint is a sensation of dryness with dyspareunia. The discharge may be watery, though, on rare occasions, bleeding may occur from the atrophic mucous surfaces.

The only treatment required is reassurance associated with the use of a simple lubricating jelly. If this does not improve the condition, estrogen may be given either as a local instillation or by oral administration.

Acute Gonorrhea

Acute gonorrheal infection usually develops within a few days following intercourse. The acute inflammation, which involves the urethra, Skene's and Bartholin's glands, and the cervix, causes profuse discharge. This creates soreness and irritation of the vulva which is aggravated on voiding. The history and physical findings suggest the diagnosis. Smears of pus obtained from the urethra or cervix may reveal the gonococcus, an intracellular gram-negative diplococcus, but cultures should be taken for positive diagnosis. Blood specimens should be sent for serologic study. However, therapy should be immediately instituted and penicillin is specific. Proof of cure includes subsidence of the inflammation and repeatedly negative smears and cultures taken at weekly intervals and after menstruation.

It is advisable to have the patient in the hospital for a few days for bed rest and for antibiotic treatment which can then be given under careful supervision. The aim is to control the infection before it invades the upper genital tract. All contacts if possible should be identified and treated.

Chronic Gonorrhea

Chronic gonorrhea of the lower genital tract is difficult to diagnose. The history of acute illness, infection of the male partner by intercourse, and the presence of residual inflammatory changes in the lower or upper genital tracts are suggestive. Positive smears and cultures from the cervical discharge are difficult to obtain unless there is an acute exacerbation appearing after a menstrual period or in association with pregnancy. A new infection must be excluded in both these instances.

ABDOMINAL PAIN IN PREGNANCY

Abdominal discomfort or pain is a very common complaint during pregnancy. In most instances this is fleeting in character and not of serious consequence. There are other pains, however, which cause more distress. While most of these pains are peculiar to pregnancy and involve the uterus, the appendages, and supporting ligaments, it must be emphasized that a pregnant woman may develop any acute surgical condition. Furthermore, because of the stretching of the abdominal wall and displacement of abdominal organs due to the enlarged uterus, the classic symptoms and signs may be obscured and the true diagnosis delayed.

An important point has been stressed about pyrexia when one is dealing with acute abdominal pain in pregnancy. It has been observed that the onset of abdominal pain associated with pyrexia is due to some conditions outside the pregnant uterus; but the absence of early pyrexia does not, of course, exclude extrauterine lesions, either obstetric or surgical. An infected abortion and a degenerating fibroid are exceptions to this rule.

Nausea and vomiting of early pregnancy, when associated with vague abdominal pains or intestinal colic, may suggest the diagnosis of acute appendicitis, unless the menstrual history is elicited. The consequences are more serious, however, if the nausea, vomiting, and pain caused by an acute appendicitis are attributed to an associated early pregnancy.

As a matter of convenience the pregnant period is divided into trimesters, and various

conditions which are encountered in each trimester follow.

First Trimester.—A frequent complaint of early pregnancy is that of recurring sharp pains in both lower quadrants. They usually occur when the patient moves suddenly and are thought to be due to *tension on the round ligaments*. These pains tend to disappear when the enlarging uterus becomes more fixed.

Constipation is very troublesome during this time and may alternate with attacks of intestinal colic and diarrhea due to dietary indiscretions or purgation.

Abortion and *ectopic pregnancy* are most common in the first 3 months. Abortion of an intrauterine pregnancy begins with lower abdominal discomfort, regular uterine contractions develop, vaginal bleeding increases, and as the cervix dilates the products of conception are expelled, either completely or incompletely. When intrauterine or pelvic infection follows, the clinical picture is that of a pelvic peritonitis. Attempts to induce criminal abortion cause symptoms and signs which are most atypical. *Hemorrhage* and *pelvic peritonitis* are perhaps the most common complications. *Ectopic pregnancy* is the most frequently misdiagnosed gynecologic disease! Bleeding from a corpus luteum of pregnancy simulates an ectopic pregnancy, but the acute signs and symptoms rapidly subside.

The pregnant uterus is often found to be retroflexed and retroverted in the first 8 weeks, but usually between the 8th and 12th weeks spontaneous correction occurs. If the retroversion persists, impaction in the pelvis may result, and this may create very acute symptoms. Acute lower abdominal pain and retention of urine develop in a woman who is known to be pregnant. Overflow incontinence occurs. The large tender bladder is palpable and must not be mistaken for the enlarged uterus. On pelvic examination, the cervix is drawn up under the symphysis, and the impacted, retroverted uterus fills the pelvic cavity. After the bladder is drained, it will be apparent on bimanual examination that the pelvic mass is the uterus. Its position, as a rule, becomes corrected spontaneously with sedation and posture if the bladder is kept empty.

A *pelvic hematocoele* or an *ovarian cyst* always displaces the uterus, and therefore the

latter is felt separate from the mass. A cervical fibroid produces pain, retention of urine, and displacement of the cervix, but the symptoms and signs of pregnancy are not present.

Second Trimester.—In pregnancy, *physiologic distention and dilatation of the ureters* cause stasis of urine, and acute pyelitis is a frequent complication. Right-sided pyelitis is more common. Ordinarily the symptoms, signs, and urine analysis are diagnostic. Subacute renal infection may give rise to less typical symptoms and signs which are referable to the back or upper abdomen. This type of pyelitis may remain undiagnosed unless an acute exacerbation develops and a more complete renal tract investigation is made.

Renal calculi may cause attacks of colic for the first time during pregnancy. The symptoms and signs suggest the diagnosis, and this is verified by routine investigation.

Acute appendicitis in pregnancy is a serious complication. An attack, very rarely the first, is most likely to develop in the first or second trimester but may occur later. Nausea, vomiting, and abdominal discomfort, associated with the increased white cell count and rapid sedimentation rate, all normally present in pregnancy, tend to obscure the diagnosis. After the 5th month, the anatomic displacement of the cecum and appendix gives rise to atypical physical signs. An acute pyelitis of the right kidney must be excluded.

Once an acute appendicitis is diagnosed, operation is imperative. If there is peritonitis present, the chance of abortion or premature labor ensuing after operation is increased, and the maternal prognosis is more grave. It is important to note that peritonitis may cause uterine spasm which simulates the clinical signs of concealed retroplacental hemorrhage.

Perforation of a peptic ulcer during pregnancy has been reported. A diagnostic aid in the history of prior investigation or treatment for a suspected ulcer.

Intestinal obstruction due to adhesions from previous operations may occur as the adherent intestinal coils are displaced and kinked by the enlarging uterus. Paralytic ileus is a rare complication of acute pyelitis with pregnancy.

More commonly, acute abdominal pain in pregnancy is caused by *degeneration of a*

fibroid or by an *ovarian cyst* which has undergone torsion, intracystic hemorrhage, or rupture. Such pelvic tumors are usually identified at antenatal examination, and the fact that their presence is already known aids in the diagnosis and treatment when complications develop.

A fibroid complicating pregnancy is ordinarily treated conservatively until the child is close to term. The treatment then is an obstetric problem. An ovarian cyst associated with pregnancy should be removed by operation at a time when abortion is least likely to be precipitated but before the bulk of the pregnant uterus makes the operation difficult.

A *hematoma in the rectus sheath* is a rare accident which occurs in the second trimester of pregnancy or later. The rupture of the muscle or blood vessel is usually caused by unusual muscular stress. The sharp pain and the tense abdominal wall with very acute local tenderness create a surgical emergency. The findings on abdominal palpation and pelvic examination while under the anesthetic clarify the diagnosis, which is fully established when the hematoma is incised on opening the abdominal wall.

Third Trimester.—Again, in the third trimester, the patient may complain bitterly of discomfort due to the *pressure of the enlarged uterus*. This, of course, is aggravated if an acute hydramnios or a multiple pregnancy is present. Fetal movements may make certain points on the uterus very tender. Pain in the liver region in a patient with toxemia of pregnancy is a warning symptom of an impending eclampsia.

Retroplacental hemorrhage, if small, causes considerable distress which may subside in time. If the concealed hemorrhage is large, the distention of the uterus becomes marked, acute severe pain is present, and a state of shock ensues. There is usually an associated toxemia of pregnancy or a history of local trauma. On palpation the uterus is distended, hard, and tender. The fetal heart sounds are absent.

Rupture of the pregnant uterus is a serious occurrence which usually happens near term or during labor. *Spontaneous rupture* is more common, and it is so frequent in cesarean

section scars, whether in the upper or lower segment, that the dictum, "once a section always a section," is almost a rule. An obstructed labor will end in rupture of the overdistended lower uterine segment if it is not recognized and treated. The unwise use of Pitocin in labor before the cervix is dilated may be the cause. *Traumatic rupture* may result from external trauma such as blow on the abdominal wall or a crushing injury. More frequently it is a direct result of forceful obstetric procedures such as internal version late in labor.

If the patient is in labor, the contraction cease and abdominal pain and tenderness develop. Shock with evidence of internal hemorrhage ensues, the fetal parts will be easily palpable, and the fetus usually dies. If the rupture occurs during delivery, the third stage is abnormal; there is delay in expression of the placenta, postpartum hemorrhage, and progressive shock. The diagnosis will not be made until one explores the uterine walls by a bimanual examination.

Rarely an *extruterine abdominal pregnancy* survives to the last trimester, and abdominal pain and discomfort are distressing. The diagnosis is rarely made before the abdomen is opened because of the abdominal symptoms or for a proposed cesarean section.

The pain of abortion or the pain due to the onset of premature labor or labor at term are usually obvious and remain the most common causes of abdominal pain in women of the childbearing age, despite the misleading history sometimes given by the patient.

Chapter 29

Hernia

W. Mason Couper, MD

Hernia may be defined as a protrusion of a viscus or a part of a viscus from the cavity in which it is normally contained through a congenital or acquired aperture or weakness. Subsequent descriptions will be restricted to types of abdominal hernias, e.g., inguinal, femoral, umbilical, and postoperative.

CONSIDERATIONS OF TERMS COMMON TO ALL HERNIAS

A *reducible hernia* refers to one in which the contents of the hernial sac can be replaced into the cavity from which they protruded, while an *irreducible hernia* is one in which the contents of the hernial sac cannot be so replaced.

An *incarcerated hernia* or obstructed hernia is one in which the hernial mass is irreducible. There is obstruction to the flow of intestinal contents in the occluded loop, but the blood supply and lymph drainage remain intact.

A *strangulated hernia* is one in which the blood supply and lymph drainage of the hernial contents are partially or completely occluded. This condition will result in gangrene unless relieved within a few hours.

INGUINAL HERNIA

Embryologic Features.—In the male, the close association of inguinal hernia with the descent of the testis necessitates a review of the embryologic features and the path traveled by the testis in its descent. The testis develops

as a retroperitoneal structure in the region of the kidney. During its descent it carries with it a tube of peritoneum through the inguinal canal and into the scrotum. This protrusion of peritoneum is known as the *processus vaginalis*. Before birth, this processus becomes obliterated throughout its length, except for that portion which surrounds the testicle. This portion is known as the *tunica vaginalis*. When the processus vaginalis remains patent, there is a direct communication between the peritoneal cavity and the scrotum. The patent processus constitutes the potential sac for a future hernia.

Acquired and Congenital Factors Governing Inguinal Hernia.—In the male the majority of indirect inguinal hernias are considered to be congenital in origin. The peritoneum of a patent processus vaginalis has been found in 35% of infants up to the 4th month, and many adults carry with them throughout life, a patent funicular process. Factors such as coughing, straining, lifting in the adult and crying in the child all tend to raise the intra-abdominal pressure and so put a strain on a partially closed or a poorly obliterated processus vaginalis, with the development of a hernia. Unilateral or bilateral hernias are common in infants with *phimosis* or *pin-point meatus*.

Classification of Inguinal Hernia.—There are two main types.

- 1 *Oblique or indirect inguinal hernia*
- 2 *Direct inguinal hernia*

There is a combination of the above types which may fall into a third group and is known as direct-indirect type of inguinal hernia. The protrusion is to both sides of the inferior epigastric artery.

Oblique or Indirect Inguinal Hernia

Oblique hernia is so designated because of the oblique course the hernia takes in passing through the inguinal canal. The indirect hernia has been described according to the degree of patency of the funicular process. Where the

process is open down to the testicle, the condition is described as the *congenital* or *testicular type*. When the distal portion of the processus has been obliterated with patency of the proximal portion, it is described as the *funicular type*.

Again, there are cases in which the proximal and distal portions of the processus are obliterated, and a small intervening portion remains patent. This gives rise to a collection of fluid along the cord, cystic in nature, which is described as an *encysted hydrocele of the*

Fig 358—Anatomy of the inguinal canal.

Fig 359 —Types of inguinal hernia and anatomy of the posterior wall of the inguinal canal

Fig 360 —Congenital anomalies of processus vaginalis.

cord. The cystic area may be unilocular or multilocular.

Oblique inguinal hernia occurs much less commonly in females than in males. The patent peritoneal diverticulum in the female corresponding to the processus vaginalis is called the canal of Nuck.

Coverings of Indirect Inguinal Hernia.—The covering layers are as follows:

- 1 The skin
- 2 Superficial fasciae
3. Intercolumnar fascia from external oblique aponeurosis
4. Cremasteric fascia
5. The transversalis or infundibuliform fascia
- 6 The extraperitoneal connective tissue

Fig 361.—Left complete (scrotal) inguinal hernia

The separation of the coverings into layers will not be possible in the old, long-standing hernia, as the layers become fused together.

Contents of Sac.—Practically every abdominal organ, with the exception of the liver and pancreas, may, at one time or another, descend into the hernial sac. When the sac in the oblique type contains loops of small bowel, the hernia is known as an *enterocele*. At times the omentum forms the only structure within the sac, and this condition is described

as an *omentalocele*. Occasionally a part of the wall of the small bowel is caught in such a way that only a portion of its lumen is occluded; this is known as *Richter's hernia*. When a Meckel's diverticulum is found in the hernial sac, it is known as *Littre's hernia*.

Clinical Features and Diagnosis.—At the onset, the characteristic feature is a dragging sensation in one or the other groin. Following this pulling and dragging sensation a lump appears as a rounded swelling just above Poupart's ligament and lateral to the spine of the pubis. Straining, coughing, and running make the lump more obvious. On lying down, the swelling usually disappears. When the swelling emerges at the external ring, the

Fig 362.—Right complete (scrotal) inguinal hernia, operation demonstrated a hernia-en-glissade (sliding hernia).

condition is named an *incomplete inguinal hernia*, and when it descends beyond the external ring to gain the scrotum, it is designated a *complete or scrotal hernia*.

Examination of the patient is usually carried out with the examiner seated directly in front of the subject. The clothing is removed from the umbilicus to the knees. When the patient is asked to cough, a swelling may be

seen in one or the other inguinal region. With the examining finger introduced into the inguinal canal (by invaginating the neck of the scrotum through the external ring), a definite impulse may be palpated after coughing, or at times the examining finger is displaced beyond the external ring by the hernial protrusion. The course and obliquity of the hernia allow one to appreciate the indirect type. Symptoms of pain referred to the testicle of that side or gastrointestinal disturbances with occasional nausea are generally due to traction by a large hernia on the mesentery. Percussion of the hernia may enable the examiner to distinguish between intestine or fluid in the sac. A resonant note, on percussion, suggests gas in the intestines. The clinical differentiation between the oblique inguinal hernia and the direct type, by the palpation of the inferior epigastric artery, is extremely difficult and therefore cannot be relied upon as an important point in making the differentiation between these two types of hernia. More significant is the diffuse bulge passing directly forward from the peritoneal cavity characteristic of the direct type.

Differential Diagnosis of Inguinal Hernia.—

Inguinal adenitis. A mass somewhat oval in shape presents in the groin. It is tender and painful and usually moves freely under the skin. Occasionally other lymphatic nodes in the neighborhood, showing some enlargement and tenderness, are noted. The inguinal canal is found empty on examination, and the enlarged node or nodes are palpated to one or the other side of the canal.

Ectopic testis or a partially descended testis may appear as an irreducible swelling in the inguinal region. This condition is readily recognized by the shape and consistency of the tumor, by the testicular sensation experienced by the patient when the swelling is compressed, and by the fact that no testis is present in the corresponding side of the scrotum.

Lipoma of cord consists of a soft lobulated fatty mass, not tender, not increasing greatly in size, and usually present for a considerable period of time.

Encysted hydrocele of cord appears as a tense oval tumor, attached to the cord mass when the cord is made taut by traction on

the testicle. It may be readily palpated in the external inguinal ring. The cyst can be transilluminated, which fact makes the diagnosis an easy one.

Psoas abscess may present just above Poupart's ligament or extend beyond it. The swelling is soft and fluctuant and may be diminished in size by compression. It is dull to percussion and gives a slight impulse on coughing. Clinical and radiologic examination of the spine will disclose the source from which the abscess originated.

Fig. 363.—Congenital indirect inguinal hernia in a female patient. (Note descent of hernial mass into labium majus.)

Hematoma of the cord. A history of injury, with ecchymosis of the skin above Poupart's ligament and with swelling along the cord, usually enables one to make the diagnosis of a hematoma due to trauma.

Treatment of Indirect Inguinal Hernia.—

Three methods have been used:

1. Mechanical, by use of truss
2. Surgical repair
3. Fibrosis of the sac by injection of solutions

Use of Truss—This method has been used since ancient times, and the use of a type of bandage or belt has always been associated with the early references to hernia treatment. Not all inguinal hernias are suitable for operation, and although there are many difficulties attending the use of trusses, there are, nevertheless, indications.

For the use of a truss for the infant, see Chapter 30.

Adults are less likely to obtain a cure from the wearing of a truss but may derive considerable benefit by having well-fitted support. The adult should remove the truss after retiring and put it on before getting out of bed. It is preferable to wear the truss next to the body. Any underclothing beneath the pad does not facilitate proper fitting and encourages the hernia to slide down beneath or to one side of the truss. Should the hernia become irreducible, the truss cannot be worn. Trusses are contraindicated in cases of obesity, hydrocele, varicocele, and incomplete descent of the testicle. For those patients with a chronic cough or in the presence of a large hernia, it may be advisable to wear the truss at night. Irritation of the skin caused by the pad of the truss can be overcome by careful bathing and dusting the area liberally with talcum powder. Attention should be paid to the cleansing of the truss itself. When a truss is properly fitted, it should be worn without discomfort, and the patient should be able to stand up, bend down, cough, and do his work without protrusion of the hernia around the pad.

Surgical Treatment of Inguinal Hernia.—The fundamental principles which underlie the surgical repair of inguinal hernia are thorough exploration of the canal, identification and excision of the peritoneal sac, and repair of the canal floor, or reconstruction of the defect in the abdominal wall.

The methods of carrying out the surgical repair are many and varied. Indeed, practically every known procedure has been either rediscovered, modified, or rewritten in an effort to seek the perfect repair. No attempt will be made to review or describe the many modifications and methods by which a repair of the inguinal canal can be accomplished. Several well-recognized standard procedures will be used to illustrate the underlying principles.

The *Bassini operation* embodies two main principles: removal of the hernial sac and repair of the defect in the posterior wall of the canal.

The operation is carried out by making an incision, parallel with Poupart's ligament and one-half inch above it, extending from the spine of the pubis to beyond the internal ring (one-half inch above the midpoint of Poupart's ligament). Camper's fascia, represented by the thick subcutaneous yellow fat, as well as the deeper Scarpa's fascia, is divided to expose the shiny aponeurosis of the external oblique muscle. The external ring should be isolated. At times the clear outline of the margins of the external ring cannot be seen, but the edges can be readily palpated by introducing the finger along the course of the cord where it emerges at the pubic spine; by following the cord upward, the prominent edges of the ring can be palpated. Now the aponeurosis is divided in the direction of its fibers downward through the external ring and upward to just beyond the internal ring. The ilio-inguinal nerve will then be seen running along the cord lying on the cremasteric fibers. The cremasteric fibers are separated to expose the cord with its accompanying vessels. The sac in an indirect oblique hernia is found lying superficial to the vas. It is picked up and dissected from the surrounding structures. The neck is cleaned. The sac is opened and inspected for contents. The contents if viable are reduced. When strangulated nonviable bowel is found, it is resected. Adherent omentum is dissected free and returned to the abdominal cavity. To close the neck, a transfixion suture is used, or, if the neck be wider than two fingerbreadths, a purse-string suture may be used. The redundant part of the transfixion sac is excised. The second phase in the operation consists of a repair of the defect in the posterior wall of the canal. This is carried out by suturing the conjoined tendon down to the reflected edge of Poupart's ligament posterior to the cord. The external oblique is then closed over the cord and the superficial fasciae and skin sutured to complete the procedure.

Halstead added a modification to the above method by transposing the cord superficial

to the sutured external oblique aponeurosis. In this way the posterior wall is given added strength by the use of the external oblique aponeurosis. In his earlier work, like Ferguson, he did not transpose the cord but sutured the conjoint tendon to Poupart's ligament, anterior to the cord except at the level of the external ring where an opening was left for the passage of this structure.

ligature of the sac and its excision close to the internal ring. Closure of Scarpa's fascia and the skin is all that is necessary.

Where a very large inguinal hernia exists the external and internal rings may come to lie across one another, thus leaving a large defect in the posterior canal wall to be repaired. It is in this type that modifications of the above methods are used. The use of

Fig 361—Bassini repair of indirect inguinal hernia

In the treatment of an oblique hernia in a very young infant or child, the procedure of high ligation of the sac is widely practiced. No attempt is made to disturb the contents of the inguinal canal. The sac is picked up at the external ring and freed at this point from the cord and vessels. Sufficient cleansing can be carried out at this level to permit the

living fascia as strands to interlace the defect has been described by McArthur and Gallie. A large variety of materials has been used to overcome the defect—floss silk has been woven through the defect, also filigree wire, and lately tantalum or stainless steel mesh or skin have all been used in selected cases.

Sliding Hernia or Hernia-en-Glissade

This type can be defined as a hernia in which the posterior wall of the sac consists of the cecum on the right side or the pelvic colon on the left side. It is found in the inguinal region and is brought about by the slipping, in a downward direction, of the viscus and the posterior parietal layer of peritoneum.

Symptoms and Diagnosis.—*Sliding hernia* of the large intestine is generally of the indirect inguinal type. It occurs in males over the age of 45 years and is more common on the right side. The condition, however, does occur quite frequently on the left side. Typical examples are shown in Figs 364 and 366. If the hernia is reducible, the symptoms are very similar to those found in the ordinary inguinal hernia, with the exception that the sac is somewhat larger. The internal ring becomes stretched and lies over the external ring so that reduction of the hernia is usually easy, and strangulation seldom occurs. As the signs are not well defined in this type of hernia, the diagnosis is not made until operation. On the left side, the presence of the colon in the sac may give rise to symptoms of constipation. The diagnosis may, at times, be established by radiologic examination of the colon, the barium being seen in the hernial sac. Intestinal obstruction, following such a procedure, can occur with the barium becoming inspissated in the herniated colon. This is more likely to occur when a free loop of sigmoid has descended into a left inguinal hernial sac. The condition is not a true sliding hernia which usually involves the lower part of the descending colon.

Treatment of Sliding Hernia.—The use of a truss is not satisfactory in this type of hernia because of the large size of the hernial opening. Radical operation is the treatment of choice. The exposure of the sac is the same as in the ordinary type of inguinal hernia. In this type, the bowel forms the major portion of the posterior wall of the sac. Accidental opening of the colon can easily occur while exposing the sac. The redundant portion of peritoneum is cut away and the colon mobilized to allow it to be returned to the abdomen. The repair of the defect is difficult. Many

writers suggest opening the abdominal cavity and fixing the colon to the posterior abdominal wall. Others complete the repair by bringing the conjoined tendon down to the reflected edge of Poupart's ligament, as in the ordinary oblique inguinal hernia.

Recurrence is very common following the repair of this type of hernia because of the extensive defect and the tendency of the viscus to slip down again.

Fig. 365.—Demonstration of sliding hernia by use of barium enema (Note descent of descending colon into scrotum.)

Direct Inguinal Hernia

A direct inguinal hernia is one in which the protrusion takes place through Hesselbach's triangle. This triangle is bounded medially by the lateral border of the rectus abdominis, below by Poupart's ligament, and laterally by the inferior or deep epigastric artery. The hernia is rarely if ever on a congenital basis. It may be unilateral or bilateral. It is almost entirely confined to males after the fourth decade. It is thought to be due to weakness in the transversalis fascia with atrophy of the conjoined tendon.

Clinical Features and Diagnosis.—There is an oval swelling in the groin, which presents above Poupart's ligament. The swelling increases in size on coughing and if reducible, disappears on lying down. On examination, the finger, when inserted into the external

inguinal ring, gives the examiner the sensation of going directly back into the abdomen, whereas in the indirect type, the finger takes an upward course along the inguinal canal. The swelling rarely descends into the scrotum. There is a dragging sensation but less pain than in the indirect type. At times it is impossible to differentiate between the two types; the final diagnosis is made at operation. Palpation of the deep epigastric artery to distinguish between the indirect and direct types is seldom possible and rarely can be relied upon in establishing the diagnosis. The differential features are those described in the oblique type.

Fig. 366.—Direct inguinal hernia.

Treatment of Direct Inguinal Hernia.—In selected cases, conservative methods, such as the wearing of a truss, may suffice, but the majority of these cases come to operation. The operative features follow the pattern described under indirect hernia, except for the handling of the sac. When small, it need not be excised but may be pushed back through the defect in the transversalis fascia by invagination, with repair of the fascial defect. The conjoined tendon is sutured to Poupart's ligament over the invaginated sac beneath the cord. When a larger sac is present, it should be opened and the redundant tissue excised. The peritoneal defect is then closed. The re-

maining features in the repair are as described previously.

The combined direct-indirect inguinal hernia is converted into a true oblique type and dealt with as such.

Complications Following Operative Repair of Hernia.—Careful preoperative care and thorough cleansing of the area before operation do a great deal to lessen the incidence of wound infection. The introduction of antibiotics has further helped to reduce this problem, and the practice of giving an antibiotic routinely is used by many surgeons. The use of nonabsorbable suture material (silk, cotton, or wire) results in less post-operative tissue reaction and a lower recurrence rate. Occasionally sinuses may supervene if infection occurs from the presence of this foreign material.

Hematoma is one of the more frequent complications of *herniotomy*. It is most common after the removal of the large scrotal sac. The hematoma may be confined to the cord or to the inguinal canal, or subcutaneous tissues, or it may be large and fill the scrotum. If it is extensive, the wound should be opened at the earliest moment and the blood evacuated. Chemotherapy should be routine used to prevent secondary infection.

Lung complications, mostly due to atelectasis, may develop. It has been found that these complications occur least with general anesthesia and somewhat more frequently with spinal and local infiltration. Pulmonary embolism has occurred.

The later complication of *recurrence* of the hernia varies a great deal from clinic to clinic, the percentage of recurrences ranging from 5-20%. The mortality rate is low in this operation, being under 1%. This, of course, does not include the cases of inguinal hernia complicated by bowel obstruction or strangulation.

FEMORAL HERNIA

A femoral hernia is one in which the hernial protrusion takes place through the femoral ring into the femoral canal.

The boundaries of the femoral ring are medially the lacunar (Gimbernat's) ligament, laterally the femoral vein, posteriorly the

ramus of the pubis, covered by the pectineus fascia and ligament, and anteriorly the inguinal ligament.

Etiology, Sex, and Incidence.—Femoral hernia is found much more frequently in females than in males, in the ratio of 3:1. The condition is rarely found in children. When present in adults it may be unilateral or bilateral.

The etiology of the development of femoral hernia, on a congenital basis, is not so universally accepted as in the case of indirect inguinal hernia. There are many who feel there is, in this type of hernia, a preformed pouch or peritoneal diverticulum which has

the sac, it may be overlooked altogether in obese patients. The hernia appears as a small globular swelling just lateral to the spine of the pubis and below Poupart's ligament. Unless the sac contains intestine, there may be very little increase in size on coughing, and when the patient lies down, the contents of the sac may reduce slightly but never completely disappear. There remains a small fatty nodule after the main contents of the sac have been reduced. This remaining nodule may represent the fatty plug filling in the femoral ring along with the large lymph node at the apex of the femoral canal (gland of Cloquet). Pain is not a prominent feature, but if omentum or intestine is contained in the sac, the patient may complain of a dragging sensation or colicky pain. The pain usually radiates down the anteromedial aspect of the thigh. Gurgling may be heard and felt if intestine is present in the sac. Strangulation in this type of hernia is more common than in the inguinal variety because of the small size of the ring and the rigidity of the surrounding structures. Richter's hernia, in which only a part of the lumen is caught by the femoral ring, is more likely to occur in femoral than in any other variety of hernia.

Differential Diagnosis.—Those conditions most commonly mistaken for femoral hernia are saphenous varix, incomplete inguinal hernia, psoas abscess, and regional lymphadenopathy.

The *saphenous varix* disappears when the patient lies down and can be readily compressed by gentle pressure over that site. There is no gurgling, but occasionally a venous hum is heard on auscultation over the area. A venous thrill may be felt on coughing. The skin may show a bluish discoloration over the saphenous varix, and there may be varicose veins on that extremity.

Progressive enlargement of a femoral hernia occurs by protrusion through the fossa ovalis, the sac being turned upward by the fascial arrangements, and the differentiation between it and an *incomplete reducible inguinal hernia* is at times difficult. Here, the inguinal hernia can be reduced by pressure exerted in an upward, outward, and backward direction, and continued pressure over the inguinal canal will prevent its descent

Fig 367—Anatomy of femoral canal

failed to become obliterated. This fact is borne out by the finding on many post-mortem examinations of a preformed peritoneal sac in the femoral canal. A great many femoral hernias, especially in the older age group, are thought to be acquired. In the older age group, the existence of lax muscles, attended by loss of weight and poor tissue tone, seems to predispose to the development of this type of hernia.

Clinical Features and Diagnosis.—The symptoms are much less marked in femoral than in inguinal hernia because the hernia is small, and if no intestine is contained in

Fig. 368—Femoral hernias of various sizes (Courtesy Queen Mary Veterans' Hospital)

The reduction is much quicker than in femoral hernia, where the necessary pressure is usually downward and medially. The inguinal hernia will be seen to lie above a line running from the spine of the pubis to the antero-superior spine, whereas the femoral hernia is found below such a line.

When a *psoas abscess* presents below Poupart's ligament, it is a soft fluctuant mass transmitting an impulse on coughing. It is reducible in some cases without any gurgling

tain cases, the diagnosis may be established only at operation.

Treatment.—The cure of femoral hernia is by operation. The tendency for this type of hernia to strangulate indicates early surgical intervention. Mechanical treatment is unsatisfactory and offers little chance of cure; however, there are cases in which, for some medical reason, operation is inadvisable and a truss may be worn. The site of this hernia makes the wearing of the truss difficult, as the pres-

Fig 369—Lipoma simulating femoral hernia on left side, small direct hernia in right groin (Courtesy Queen Mary Veterans' Hospital)

sound or sensation. Fluctuation may be present in a dumbbell-shaped abscess above and below Poupart's ligament. Examination of the spine usually reveals other evidence of tuberculosis.

Lymphadenopathy in the femoral region may give rise to difficulty in diagnosis. Here the swelling is firmer, with tenderness on pressure; usually there are other enlarged nodes in the neighborhood and a search may reveal some focus of infection about the leg or foot to give rise to the adenopathy. In cer-

sure pad can be readily displaced by the movements of the body and thigh. For these reasons the operative treatment is recommended. The operation is directed toward removal of the sac and closure of the femoral ring.

Operations for Femoral Hernia.—There are two recognized approaches for the surgical repair:

1. Inguinal route
2. Femoral route

Each method has its advocates and a brief description of each will be given.

Repair by the Inguinal Route.—This procedure was first described by Annandale and continues to retain that name. The incision is made 1 cm above Poupart's ligament and is parallel with it for a distance of 3-4". The aponeurosis of the external oblique muscle is divided in the direction of its fibers over the inguinal canal. By retracting the edges of the divided aponeurosis of the external oblique muscle, the conjoint tendon, spermatic cord, and transversalis are brought into view. Gentle retraction of the cord upward exposes the floor of the inguinal canal, which consists of the transversalis fascia. An incision is then made in the transversalis fascia along the line of the inguinal canal and over the neck of the sac. This exposes the peritoneum, which is traced to the neck of the sac, and the sac, if small, can be freed and pulled back, or reduced. The fundus of the sac is picked up in forceps and opened, and tags of adherent omentum are freed. The neck is transfixed as in the ordinary inguinal hernia operation or closed with a purse-string suture. The redundant portion of the sac is removed, and the transfixed portion is allowed to drop back into the abdomen. The opening in the femoral ring is now closed with interrupted sutures. These run from the lower margin of Poupart's ligament to the ligamentous reflection along the ramus of the pubis (Cooper's ligament), or occasionally to the pectineal fascia. Three or four sutures usually suffice to close the opening. The conjoint tendon is then brought down to Poupart's ligament, beneath the cord. The external oblique aponeurosis and skin are closed in the usual manner.

In the Lotheisen repair, the conjoint tendon is sutured behind the cord to Cooper's ligament.

Repair by the Femoral Route.—The incision is made below and parallel with Poupart's ligament over the prominent part of the swelling. The soft tissues and fat are separated to expose the sac lying embedded in the fat of the thigh. The sac is dissected free to expose the femoral ring from below, care being exercised not to damage the femoral vein lying lateral to it. The constriction about the

neck is stretched to enlarge the opening. The sac is opened with care to avoid the possibility of injuring the contents. If the sac contains omentum or intestine, this is reduced and the neck of the sac is pulled down and closed in the method described above, and the redundant portion is removed, allowing the transfixed neck to slide back through the femoral ring behind Poupart's ligament. The femoral ring is then closed by bringing the lower margin of Poupart's ligament down to the pectineal fascia.

Strangulated Femoral Hernia

Here, the inguinal approach is preferable. The peritoneum, when exposed, can be opened to identify the ring and the obstructed intestine. If the intestine is not viable, a resection is much easier to carry out than by the femoral approach. There are cases where the constricting ring cannot be overcome by this approach, and a combined inguinal and femoral exposure may be necessary in order to free the adherent mass in the femoral region. At times the constricting ring may not yield, and it may be necessary to incise Poupart's ligament to free the constriction and expose the area.

UMBILICAL HERNIA

An umbilical hernia is one in which the protrusion takes place through the umbilical ring. The majority of such hernias are congenital in origin and appear in children. The condition is caused by failure of the umbilical ring to close following the section of the umbilical cord. This type of hernia may also be acquired and appears later in life in adults.

The discussion of umbilical hernia will include what is often described as paraumbilical hernia. This type is characterized by protrusions through small fascial defects adjacent to the umbilical ring and comprises a large group of umbilical protrusions occurring in the aged or obese female.

Umbilical Hernia in the Infant
(See Chapter 30.)

Umbilical Hernia in the Adult

This term is a rather loose one, and the group includes the paraumbilical protrusions occurring through fascial defects in and adjacent to the true umbilical opening.

In the older patient, this type of hernia is usually acquired. It appears between the ages 30-55 years. The etiologic factors are increased intra-abdominal pressure, relaxation of the abdominal muscles, obesity, ascites, multiple pregnancies, and diastasis recti. The umbilical opening, being a weak point in the abdominal wall, gives way and the protrusion develops. Women are more prone than men to develop this type of hernia. The size of the hernia varies and may reach considerable proportions.

Symptomatology.—In the early case, in the obese patient, a small hernia may not be visible and is found on palpation as a rounded, firm nodule in the region of the umbilicus.

In the early stages an expansile impulse is seen when the patient coughs or strains; the tumor if reducible disappears when the patient lies down. At times the hernia appears to emerge at one or the other side of the ring and for this reason the term paraumbilical hernia has been introduced. When the hernia increases in size, it presents as an oval or rounded mass, which, as it enlarges, becomes pendulous and may reach considerable proportions. The sac becomes lobulated and irregular in outline. The contents are usually the omentum, along with the transverse colon and occasionally the small intestine. Because of the tendency of the omentum to become adherent to the walls of the sac, this type of hernia rapidly becomes irreducible. When bowel is included, peristalsis may be observed.

The patient complains of pain, usually dragging in character. Traction on the colon gives rise to attacks of colicky pain with constipation and at times nausea and vomiting, especially when strangulation develops.

Treatment.—The treatment is difficult as the majority of these patients are in the older age group, usually obese, and with poor musculature. The small hernia, if reducible, may be controlled by a truss. In the obese subject, an elastic belt may be worn. For the large hernia, operative repair is necessary except in those cases in which there are contraindica-

tions, such as cardiac or pulmonary disease. In some patients with very large protrusions, repair is inadvisable because of the danger of

umbilical hernia

Fig 370.—Pathologic conditions of the umbilicus (Complete Meckel's anomaly is often referred to as persistent omphalomesenteric duct.)

Each method has its advocates and a brief description of each will be given

Repair by the Inguinal Route—This procedure was first described by Annandale and continues to retain that name. The incision is made 1 cm. above Poupart's ligament and parallel with it for a distance of 3-4". The aponeurosis of the external oblique muscle is divided in the direction of its fibers over the inguinal canal. By retracting the edges of the divided aponeurosis of the external oblique muscle, the conjoined tendon, spermatic cord, and transversalis are brought into view. Gentle retraction of the cord upward exposes the floor of the inguinal canal, which consists of the transversalis fascia. An incision is then made in the transversalis fascia along the line of the inguinal canal and over the neck of the sac. This exposes the peritoneum, which is traced to the neck of the sac, and the sac, if small, can be freed and pulled back, or reduced. The fundus of the sac is picked up in forceps and opened, and tags of adherent omentum are freed. The neck is transfixed as in the ordinary inguinal hernia operation or closed with a purse-string suture. The redundant portion of the sac is removed, and the transfixed portion is allowed to drop back into the abdomen. The opening in the femoral ring is now closed with interrupted sutures. These run from the lower margin of Poupart's ligament to the ligamentous reflection along the ramus of the pubis (Cooper's ligament), occasionally to the pectineal fascia. Three or four sutures usually suffice to close the opening. The conjoined tendon is then brought down to Poupart's ligament, beneath the cord. The external oblique aponeurosis and skin are closed in the usual manner.

In the Lotheisen repair, the conjoined tendon is sutured behind the cord to Cooper's ligament.

Repair by the Femoral Route—The incision is made below and parallel with Poupart's ligament over the prominent part of the swelling. The soft tissues and fat are separated to expose the sac lying embedded in the fat of the thigh. The sac is dissected free to expose the femoral ring from below, care being exercised not to damage the femoral vein lying lateral to it. The constriction about the

neck is stretched to enlarge the opening. The sac is opened with care to avoid the possibility of injuring the contents. If the sac contains omentum or intestine, this is reduced and the neck of the sac is pulled down and closed in the method described above, and the redundant portion is removed, allowing the transfixed neck to slide back through the femoral ring behind Poupart's ligament. The femoral ring is then closed by bringing the lower margin of Poupart's ligament down to the pectineal fascia.

Strangulated Femoral Hernia

Here, the inguinal approach is preferable. The peritoneum, when exposed, can be opened to identify the ring and the obstructed intestine. If the intestine is not viable, a resection is much easier to carry out than by the femoral approach. There are cases where the constricting ring cannot be overcome by this approach, and a combined inguinal and femoral exposure may be necessary in order to free the adherent mass in the femoral region. At times the constricting ring may not yield, and it may be necessary to incise Poupart's ligament to free the constriction and expose the area.

UMBILICAL HERNIA

An umbilical hernia is one in which the protrusion takes place through the umbilical ring. The majority of such hernias are congenital in origin and appear in children. The condition is caused by failure of the umbilical ring to close following the section of the umbilical cord. This type of hernia may also be acquired and appears later in life in adults.

The discussion of umbilical hernia will include what is often described as paraumbilical hernia. This type is characterized by protrusions through small fascial defects adjacent to the umbilical ring and comprises a large group of umbilical protrusions occurring in the aged or obese female.

Umbilical Hernia in the Infant

(See Chapter 30.)

Epigastric Hernia, or Hernia in the Linea Alba

Epigastric hernia is a protrusion of the abdominal viscera through an opening in the linea alba. It occurs above the umbilicus and is found rarely in children. The actual protrusion is peritoneal fat which forces its way through the fascial interstices of the linea alba, at times following the perforating arteries. Once the fatty protrusion has started, intra-abdominal pressure augments its size until a real sac of peritoneum is finally pushed out from the abdominal cavity.

Symptoms and Diagnosis.—The condition may be present and give rise to no symptoms whatsoever, being found accidentally on examination. A small, soft tumor, at times no larger than the tip of one's finger, may be palpated in the midline between the xiphoid and the umbilicus. The tumor may be present just to the right or left of the midline. There may be localized tenderness. When major symptoms are attributable to this hernia, a true peritoneal sac is usually present which may contain local viscera. In lesser degrees of such herniation where symptoms are present, a careful investigation of the gastrointestinal tract should be carried out before correction of the hernia. At times, symptoms of gastric distress, nausea, belching, vomiting, and a dragging sensation in the pit of the stomach may be present. The condition may be aggravated by bending over or sneezing. When the patient lies down, the small tumor mass may be reduced, with relief of the symptoms. A small fibrous ring is palpable at times with the tip of the finger. In a large number of cases reduction cannot be carried out, and pressure on the protrusion simply mushrooms it over the fibrous opening.

Treatment.—There is little place for mechanical treatment in this type of hernia. Operative correction is carried out by making a longitudinal or transverse incision over the hernia, exposing the fatty tumor of peritoneal fat and, if small, removing it after ligating the small artery running alongside. The defect in the fascia is closed with one or two interrupted sutures. In the larger protrusions, when a tent of peritoneum is present in the ring, the neck of the sac is ligated as described for umbilical hernia, and the fascia is closed.

Hernia in the Linea Semilunaris

The semilunar line runs from the cartilage of the 9th rib to the pubic spine and corresponds roughly to the lateral border of the rectus abdominis muscle on each side. A protrusion through this line has been called *Spiegel's hernia*. This hernia generally occurs in middle life; the sex incidence is about equal. The condition is generally acquired, though some writers refer to a traumatic variety. The vast majority develop slowly and spontaneously.

The hernia is commonly small and seldom reaches in diameter more than 1". The symptomatology is not characteristic. The presence of a small lump below the umbilicus at the lateral border of the rectus muscle, which in most instances disappears when the patient lies down, is diagnostic. The treatment is surgical following the method outlined for the epigastric hernia.

Incisional or Postoperative Hernia

It is in this group that the largest number of ventral hernias occur. These hernias occur through previous operative sites on the anterior abdominal wall.

Certain etiologic factors play a part in the development of this type of hernia:

1. Postoperative infection in a wound, especially when drainage was required.
2. Improper closure of the original wound, allowing the omentum to escape between the sutures.
3. Improper suture material.

Prophylactically, the incision should be placed to avoid unnecessary damage to motor nerves, muscles, fasciae, and blood vessels.

Symptoms and Diagnosis.—The patient complains of a weakness and a bulge in the region of a previous operative scar. The symptoms are similar to those of umbilical hernia and are aggravated by exercise and coughing. The protruded mass may not reduce on lying down, and complete reduction in the larger hernia is usually impossible, since the omentum becomes adherent to the walls of the sac as in the large umbilical hernia. In the incisional hernia, the protruded mass spreads out under the subcutaneous fat tissues in such a

increasing intra-abdominal pressure which may produce severe pulmonary embarrassment. The patient should be prepared for operation by suitable dietary regime and re-education of the abdominal musculature.

The method of choice is that described by Mayo. This consists of making a large elliptical incision in a transverse direction about the umbilical mass, usually including a large area of the adjacent fat. The incision is deepened to expose the aponeurosis on both sides of the umbilicus. The hernial mass and

The fascial edges with the peritoneum are picked up and overlapped, chromic catgut or heavy silk sutures being used. The free margin of the overlapped edges is sewn down with interrupted or continuous sutures. The thick layer of skin and subcutaneous tissue is then closed, care being taken to avoid any dead space. A dressing is applied and held in place by adhesive straps or a scultetus bandage.

Fig 371—Umbilical hernia in obese patient with relaxed abdominal musculature

fat are dissected toward the umbilical ring until the neck of the sac is exposed throughout its circumference. The sac is opened near the neck, the adhesions are separated, and the hernial contents are reduced into the abdominal cavity. To facilitate reduction, the hernial ring is enlarged and a portion of adherent omentum resected. The excess margin of the peritoneal sac is cut away and the edges picked up in forceps. To close the umbilical ring, the aponeurosis is incised in a transverse direction. It is usually impossible in the large hernia to close the peritoneum as a separate layer

Fig 372—Mayo operation for repair of umbilical hernia

VENTRAL HERNIA

Any protrusion through the anterior abdominal wall, other than at the inguinal, umbilical, or femoral region, is defined as a ventral hernia.

Ventral hernias may be classified into three groups.

- 1 Epigastric hernia, or hernia in the linea alba
- 2 Hernia in the linea semilunaris
- 3 Incisional or postoperative

Epigastric Hernia, or Hernia in the Linea Alba

Epigastric hernia is a protrusion of the abdominal viscera through an opening in the linea alba. It occurs above the umbilicus and is found rarely in children. The actual protrusion is peritoneal fat which forces its way through the fascial interstices of the linea alba, at times following the perforating arteries. Once the fatty protrusion has started, intra-abdominal pressure augments its size until a real sac of peritoneum is finally pushed out from the abdominal cavity.

Symptoms and Diagnosis.—The condition may be present and give rise to no symptoms whatsoever, being found accidentally on examination. A small, soft tumor, at times no larger than the tip of one's finger, may be palpated in the midline between the xiphoid and the umbilicus. The tumor may be present just to the right or left of the midline. There may be localized tenderness. When major symptoms are attributable to this hernia, a true peritoneal sac is usually present which may contain local viscera. In lesser degrees of such herniation where symptoms are present, a careful investigation of the gastrointestinal tract should be carried out before correction of the hernia. At times, symptoms of gastric distress, nausea, belching, vomiting, and a dragging sensation in the pit of the stomach may be present. The condition may be aggravated by bending over or sneezing. When the patient lies down, the small tumor mass may be reduced, with relief of the symptoms. A small fibrous ring is palpable at times with the tip of the finger. In a large number of cases reduction cannot be carried out, and pressure on the protrusion simply mushrooms it over the fibrous opening.

Treatment.—There is little place for mechanical treatment in this type of hernia. Operative correction is carried out by making a longitudinal or transverse incision over the hernia, exposing the fatty tumor of peritoneal fat and, if small, removing it after ligating the small artery running alongside. The defect in the fascia is closed with one or two interrupted sutures. In the larger protrusions, when a tent of peritoneum is present in the ring, the neck of the sac is ligated as described for umbilical hernia, and the fascia is closed.

Hernia in the Linea Semilunaris

The semilunar line runs from the cartilage of the 9th rib to the pubic spine and corresponds roughly to the lateral border of the rectus abdominis muscle on each side. A protrusion through this line has been called *Spiegel's hernia*. This hernia generally occurs in middle life, the sex incidence is about equal. The condition is generally acquired, though some writers refer to a traumatic variety. The vast majority develop slowly and spontaneously.

The hernia is commonly small and seldom reaches in diameter more than 1". The symptomatology is not characteristic. The presence of a small lump below the umbilicus at the lateral border of the rectus muscle, which in most instances disappears when the patient lies down, is diagnostic. The treatment is surgical following the method outlined for the epigastric hernia.

Incisional or Postoperative Hernia

It is in this group that the largest number of ventral hernias occur. These hernias occur through previous operative sites on the anterior abdominal wall.

Certain etiologic factors play a part in the development of this type of hernia:

1. Postoperative infection in a wound, especially when drainage was required.
2. Improper closure of the original wound, allowing the omentum to escape between the sutures.
3. Improper suture material.

Prophylactically, the incision should be placed to avoid unnecessary damage to motor nerves, muscles, fasciae, and blood vessels.

Symptoms and Diagnosis.—The patient complains of a weakness and a bulge in the region of a previous operative scar. The symptoms are similar to those of umbilical hernia and are aggravated by exercise and coughing. The protruded mass may not reduce on lying down, and complete reduction in the larger hernia is usually impossible, since the omentum becomes adherent to the walls of the sac as in the large umbilical hernia. In the incisional hernia, the protruded mass spreads out under the subcutaneous fat tissues in such a

way that strangulation is not uncommon and, when present, manifests the symptoms of an acute intestinal obstruction with crampy pain, vomiting, and distention. The hernia may attain a considerable size and tend to hang down over the abdomen as in the large umbilical variety. The diagnosis is not a difficult one, with the history of an operation and the development of a slowly enlarging protrusion through that incision.

tantalum, and stainless steel mesh have been recommended.

DIASTASIS OF THE RECTUS MUSCLES

Diastasis of the rectus muscles is not a true hernia; it is brought about by stretching or widening of the linea alba in such a way as to separate the recti muscles. Two distinct types are found: infantile and adult.

Fig. 373.—Incisional or postoperative hernia following abdominoperineal resection. Note colostomy opening at upper end of incision. (Courtesy Queen Mary Veterans' Hospital.)

Treatment.—In certain cases considerable relief may be obtained by a properly fitted abdominal support. Curative treatment is by operation if the general condition of the patient permits. The operative procedure follows that described for umbilical hernia. The old scar is excised, the contents of the sac are reduced, and the repair of the defect is carried out by overlapping the edges. When this is not feasible, some form of patch to fill in the defect may be used. Skin, fascia,

Diastasis in the Infant

The condition is noted shortly after birth when a large oblong bulge is seen. It runs from the xiphoid to the umbilicus and is made more prominent when the child cries or strains. The child is usually undernourished or premature. The gap can be readily felt by palpation along the linea alba. No symptoms are present and no active treatment is necessary. The condition disappears as the child develops.

Diastasis in the Adult

Separation of the recti is found most frequently in the middle-aged female, who has had numerous pregnancies. The diastasis is made more prominent by raising the head and shoulders from the bed. The large gap can be easily felt with the hand placed along the midline, as the hand sinks readily into the abdominal cavity. A large number of these cases are asymptomatic, but there are some patients who complain of a weak feeling and dragging sensation in the lower abdomen.

The treatment is usually supportive or mechanical, with the aid of a properly fitting abdominal belt; but when this does not relieve the condition, operation may be necessary. It is carried out along the lines described above under ventral hernia.

RARE TYPES OF HERNIA

This group includes a number of unusual hernias which are designated by the names of the anatomic sites from which the protrusions occur, e.g., obturator, sciatic, lumbar, or perineal hernia.

Obturator Hernia

An obturator hernia is one in which the protrusion passes through the obturator foramen. The hernia leaves the pelvis, following the course of the obturator vessels and nerve, to enter the thigh at the upper and inner aspect. The relationship of the obturator vessels and nerve to the sac varies. At times the sac may be to one or the other side of the vessels and occasionally it divides and is found on both sides of the vessels. This hernia is found mostly in older women and in emaciated patients.

Symptomatology and Diagnosis.—The symptoms may be intermittent with pain along the inner side of the thigh. There is a characteristic distribution of the pain which follows the course of the obturator nerve. The pain, because of its distribution and character, has been described as the Howship-Romberg sign. When present, it is pathognomonic of the condition. The neck of the sac can sometimes be felt on vaginal or rectal examination. How-

ever, a tumor can rarely be palpated on external examination except in the case of a very large hernia. Gastrointestinal symptoms, when present, are usually nausea, vomiting, colicky pain, and constipation. This hernia is rarely diagnosed before complications arise, that is, before intestinal strangulation occurs. The leg on the side of the hernia may assume an attitude of flexion, internal rotation, and adduction to relax the associated muscles. Coughing sometimes accentuates the pain in the thigh.

Treatment.—The treatment is operative, and the best approach is by the abdominal route. This has the advantage over the obturator approach of not requiring another incision when the diagnosis has been made and carries less risk of damage to the obturator artery and nerve. By opening the abdomen with a lower abdominal incision, the obstructed intestine is easily found and examined. The portion of obstructed bowel may be replaced by gentle traction from within, aided by pressure exerted from without over the thigh. If resection is necessary, it can be carried out readily. The sac is inverted and the base transfixed. The redundant portion is cut away and the defect closed by bringing together the adjacent tissues.

Sciatic Hernia

This very rare hernia is also referred to as a gluteal or ischiatic hernia.

The sciatic hernia is one in which the protrusion occurs through the greater or lesser sciatic notch. The protrusion emerges from the pelvis and takes a downward course in the buttock, following the line of the sciatic nerve. It is covered by the gluteus maximus muscle which prevents any upward extension of the hernia. The hernia may be recognized as a hard tumor mass under the gluteus muscle. This type must be differentiated from lipoma, gluteal aneurysm, or abscess.

Symptomatology.—The symptoms are those of small bowel obstruction, and the exact diagnosis of sciatic hernia is established at operation. Very rarely a soft tumor is palpated at the lower border of the gluteus maximus muscle which exhibits an expansile impulse on coughing and gurgles on reduction. Occa-

sionally there is pain referred along the course of the sciatic nerve.

Treatment.—The treatment is operative by the abdominal route. The Trendelenburg position allows easier exploration of the pelvis in following the loop of distended bowel to the site of obstruction. Reduction by gentle traction on the bowel and at times an even pressure over the buttock by the assistant brings about a satisfactory reduction. The sac may be grasped, pulled up into the pelvis, and removed. At times an approach by the sciatic route is used.

Lumbar Hernia or Petit's Hernia

In this hernia the protrusion takes place in the lumbar region, in the space between the 12th rib and the crest of the ilium, and through Petit's triangle. There are two types:

- 1 The congenital, which develops spontaneously as a diffuse bulge in this area.
- 2 The acquired, which occurs in adults and usually follows trauma or operations in this area.

The soft mass is easily reducible, and strangulation seldom occurs. Diagnosis is easy when a bulge develops in this location which presents an impulse on coughing and a resonant note on percussion.

Treatment.—This is usually conservative with the aid of a supporting abdominal belt. There are, however, certain cases in which the abdominal symptoms of dragging pain, nausea, and vomiting necessitate an operative repair.

Perineal Hernia

Perineal hernia is one in which the protrusion takes place through the muscles and fasciae of the pelvic outlet. It is most common in women 40-60 years of age. It can occur in males where the protrusion is into the ischio-rectal space. There is no definite symptomatology; the occurrence of a soft swelling in the region of the labia and ischio-rectal fossae should include this condition in the differential diagnosis.

Treatment.—The defect may be repaired by an abdominal route or at times by a combined perineal and abdominal approach.

Maydl's Strangulated Hernia

Maydl's strangulated hernia is not really a condition to be described as a rare hernia but represents a retrograde strangulation of intestine in an inguinal hernia. The condition is brought about by a loop of small intestine passing into a sac and then back again into the abdomen, in such a manner as to resemble the letter "W." All the loops may be strangulated, or only the loop returning into the abdomen may be obstructed. The signs and symptoms are those of a strangulated irreducible inguinal hernia, and the treatment follows that for the relief of strangulation.

DIAPHRAGMATIC HERNIA

Definition.—A diaphragmatic hernia is one in which there is a protrusion of abdominal viscera into the chest through a normal or abnormal opening in the diaphragm.

Classification.—The simplest classification is as follows.

- 1 Congenital (see Chapter 30)
- 2 Acquired
- 3 Traumatic

Embryologic Considerations.—A brief description of the embryologic features in the development of the diaphragm is necessary for a complete understanding of diaphragmatic hernia. The embryo in its early stages contains one large body cavity, the celomic cavity, which in time is separated into the two larger cavities, the pleural and abdominal, by development of the diaphragm brought about by a fusion of the anterior and posterior portions derived from the ventral and dorsal muscle masses with the central tendon. If such a union fails to take place, an opening will remain on one or the other side, representing the pleuroperitoneal canal. This closure usually occurs in the 3rd month of intrauterine life. The size of these defects varies from small to very extensive openings. Indeed these openings may have a weak curtain of tissue separating the two body cavities, which in every respect represents a congenital weakness and allows one to explain why some hernias have a peritoneal sac while others have none. In other words the old saying that "all congenital diaphragmatic hernias have no sac" is not

entirely true. Occasionally congenital protrusions may occur through the normal openings in the diaphragm for the esophagus, aorta, or vena cava. See also Chapter 30

Acquired Types

The commonest type is the protrusion through the esophageal hiatus. Various authors have endeavored to classify this type into three groups. The classification depends upon the relationship of the esophagus and the posi-

the stomach remain in a fixed or normal position.

2. Hiatal hernia with nonfixation of the esophagus. The esophagus is tortuous and twisted by the upward displacement of the protruding cardiac portion of the stomach. This is the common type found especially in middle-aged women and gives rise to vague types of dyspepsia, especially after heavy meals or upon lifting or bending. Occasionally symptoms of dysphagia may develop later in the course of this condition

Fig. 376—A and B, Esophageal ampulla to be differentiated from true hiatal hernia
C, Hiatal hernia. Note protrusion shown above diaphragm

tion of its entrance into the cardia of the stomach

Three main groups have been described

- 1 Para-esophageal hiatal hernia, in which the esophagus is of normal length and its position and that of the cardiac portion of

- 3 The third type refers to that condition in which the esophagus appears shorter than usual and the stomach protrudes through the hiatal deficiency as a wedge, giving the appearance of having been sucked up into the chest

Symptomatology.—Small hiatal hernias are usually symptomless. The typical history of a moderately large hernia follows this pattern. A middle-aged, rather obese individual suffers from pain high up in the epigastrium especially after a heavy meal, with the pain referred to the back or across the precordium. There is regurgitation of sour or bitter-tasting material, especially upon bending to pick something up or to tie the shoes. Should this regurgitation persist, ulceration or esophagitis may develop with the persistence of the pain at the lower end of the sternum; indeed, if the ulceration is extensive, hematemesis may occur.

establishes the diagnosis but emphasizes the frequency with which this condition in all its stages is found. Very occasionally the diagnosis may be suspected on auscultation of the chest when gurgling is heard.

Treatment.—Unless the condition is giving rise to symptoms no actual treatment is necessary. The vast majority of hernias found accidentally need not be touched surgically. Patients with mild symptoms are treated by diet, antispasmodics, and alkali to relieve gastric acidity, and propping up in bed. The avoidance of bending or lifting may bring about symptomatic relief.

Fig 377—Traumatic diaphragmatic hernia

A, Simple posteroanterior x-ray to show bowel in left chest

B, Following barium enema. Splenic flexure shown in left chest

(Courtesy Queen Mary Veterans' Hospital)

The differential diagnosis should exclude heart disease, cholecystitis, and peptic ulceration.

Diagnosis.—The history may give the clinician the lead in establishing the diagnosis. X-ray examination with the screening of the patient in the recumbent position not only

When the hernia is large and respiratory distress or dysphagia is present, or ulceration has occurred with or without an attack of frank bleeding, or the persistence of retrosternal pain exists, surgical interference may be necessary. This procedure is usually carried out by the thoracic route, following a method described by Allison.

Traumatic Hernia

This type of diaphragmatic hernia is caused by a compression due to crushing injuries of the chest, by missiles such as bullets, or by knife wounds. Most traumatic hernias due to compression injuries occur in the dome of the left diaphragm. The right half of the diaphragm is rarely the site of a hernia because of the protection afforded it by the right lobe of the liver. The traumatic hernia has no sac. The viscera which protrude into the chest consist of the neighboring organs, usually the stomach, colon, spleen, and small bowel.

hernia apply. Symptomless hernia may not need treatment. On the other hand, large protrusions with gastrointestinal or respiratory symptoms require surgical intervention. This may be carried out by a thoracic or abdominal approach, or in some cases a combined approach may be necessary to bring about reduction and repair.

INTERNAL HERNIA

Definition.—An internal hernia is one in which there is protrusion into one of the peri-

Fig. 378.—Paraduodenal fossae. A, Superior; B, Inferior.

Symptoms.—These are varied. Many such hernias are discovered accidentally by routine chest x-rays. At times symptoms of intestinal obstruction affecting one of the herniated loops in the chest may be the first indication of such a condition. At times severe dyspnea may follow a recent rupture of the diaphragm.

Treatment.—Here the rules governing the handling of other types of diaphragmatic

hernia apply. This type of hernia is extremely rare and its presence is seldom diagnosed preoperatively. The condition is either found at autopsy or following laparotomy for intestinal obstruction.

There are several varieties of internal hernia. The classification follows the anatomic distribution in the abdominal cavity of various peritoneal fossae or pouches.

Classification.—

1. Paraduodenal
2. Pericecal
3. Intersigmoid

Internal hernias are most common in the neighborhood of the duodenojejunal flexure. In such cases the small bowel is invaginated into one of the inconstant peritoneal fossae found due to abnormal development in relation to the ligament of Treitz

Symptomatology.—A large number of cases do not give rise to any symptoms and are found accidentally on post-mortem examination. Usually the condition is found when laparotomy has been performed because of signs of an acute abdomen or the onset of intestinal obstruction.

Diagnosis.—The diagnosis may be suspected but is rarely made before operation. A large mass of distended loops of small intestine may present as a cystic swelling in the upper abdomen and percussion will give a tympanic note in such cases.

Treatment.—Here the management depends on what the surgeon encounters at operation. Usually on opening the abdomen the absence of small intestine in the neighborhood leads one to suspect an internal hernia. By gentle traction the small bowel may be reduced and the opening in the mesentery closed with several interrupted sutures. Failing an easy reduction by traction, the neck of the sac may require gentle stretching to widen it. One must be extremely cautious and appreciate the dangers of incising the rim of the opening in the region of the duodenum because of the important vascular structures in the vicinity, i.e., inferior mesenteric artery and vein and the left colic artery. The viability of the bowel will determine what further procedures are necessary.

INJECTION TREATMENT OF HERNIA

It was thought possible to cure hernia by the injection of a sclerosing solution into and around the neck of the sac, and successful obliteration of the sac has been reported in selected cases, particularly of the indirect in-

guinal type. The complications, however, which may follow the injection of sclerosing fluids in the vicinity of delicate structures, such as the spermatic cord, have diminished the popularity of this method of treatment.

Pediatric Surgery

Gordon M. Karn, MD, and Harvey E. Beardmore, MD.

INTRODUCTION

The purpose of this section is to present the special considerations that must be given to the infant and child as a surgical patient. Pediatric surgery as an entity is relatively recent and indicates that the child does present a different surgical picture from the adult. The principles of general surgery apply to the treatment of the young patient. However, just as pediatrics, itself, has become a division of general medical care, it has been recognized that the child demonstrates surgical conditions and reactions to surgery which differ from the adult. With the increased interest in the surgery of childhood and the selected population of a children's hospital, more and more of the congenital anomalies previously considered rare are being recognized and treated successfully. Several of the surgical conditions of importance to the child have already been included in other sections of this text. Those that have been treated fully are omitted here.

Congenital anomalies constitute a portion of the interesting conditions that are peculiar to pediatric surgery. Certain of the anomalies still are gross aberrations of nature and cannot be salvaged to give a normal individual. These must be accepted as such. Some anomalies, such as atresia of the bowel, diaphragmatic hernia, or omphalocele, present as newborn surgical emergencies. If the condition is recognized and treated promptly, the child can survive to lead a normal, healthy

life. Other anomalies are compatible with life but represent a constitutional defect of varying degree. These are usually recognized early in infancy or may not become apparent until the child is older. When the diagnosis of a congenital anomaly is made, it is important to look for other coexistent anomalies.

The child also shows a number of acquired conditions which are predominantly found in the younger ages. These may be traumatic, infectious, or neoplastic.

THE CHILD AS A SURGICAL PATIENT

The general approach to the child as a patient presents a different problem from the adult. Patience and gentleness are particular essentials in the treatment of the child. Every effort must be made to obtain and preserve the confidence of the child. The parents can be of great help in this regard if they are aware of the treatments that the child requires; then if the child can comprehend, he should be told in simple terms that a procedure may be painful or that he is going to be put to sleep, but that he will be better when it is over. There can be no compromise in the execution of essential procedures. The history in most cases depends on the observations of the parents or nursing staff and must be carefully evaluated. Physical examination and treatment require the cooperation and coordination of the patient, parents, nursing staff, and surgeon.

Age

The age of the child per se is no contra-indication to operation. It is now common experience that major surgical procedures can be well tolerated in infancy if the child is adequately prepared, the surgery is done with care, and the postoperative care gives meticulous attention to the patient's requirements. In general, once surgery is indicated, specific treatment should be anticipated. Certain conditions are emergencies and must be treated as such. Other conditions may require delay until adequate growth has taken place. In some, a proper balance must be reached between the effect of the condition or defect on the child and an adequate growth of the part. This is seen in the treatment of cleft palate and cleft lip. It is also a factor in some of the skeletal deformities where osteotomy may be the considered form of treatment. Age may also affect the reaction of the child to the presence of an abnormality which sets him aside from other children. Psychic as well as physical reaction of the patient must be considered.

Prematurity may be a complicating factor in the surgical treatment of an infant, but again if the problem is understood it is no contra-indication to necessary surgery. These children are very labile in their reactions to changes in temperature, fluid, electrolyte balance, susceptibility to infection, and nutrition. Premature infants also pose a problem in the technical treatment. Surgery must be careful and gentle. Efforts at postoperative maintenance may be laborious and tedious.

Preoperative Preparations

The child must be prepared mentally and physically for operation. His natural fears and anxieties must be allayed. Parents and hospital staff can help considerably by presenting an unflurried and confident front. The child will have apprehensive questions. These can be answered simply and truthfully. Careful step-by-step explanations in terms that he can understand will be accepted. A child will cheerfully blow up a balloon although he may not otherwise tolerate an anesthetic mask suddenly thrust over his face.

Physically the child should be in optimum condition for surgery. For elective procedures, nutritional deficiencies should be checked and, if present, corrected. The hemoglobin should be 10.0 Gm. or more. Newborn infants should be given a prophylactic dose of vitamin K to counteract their bleeding tendency. Fluid and electrolyte balance should be normal. This is particularly important in infants as they can develop imbalance very rapidly. A history of diarrhea or vomiting is important in this regard. Physical signs of laxity of the skin with dryness and loss of turgor, sunken eyes and fontanels, dry tongue, and the presence of acetone in the urine all point to dehydration. Persistent vomiting and abnormal respirations may indicate electrolyte imbalance. These must be corrected before surgery is performed. The child should have no feeding immediately prior to surgery. The last feeding should be given no less than 8 hours before operation. Clear fluids, such as 10% glucose and water, may be given up to 4 hours before operation. This is particularly important in infants to prevent depletion of their liver glycogen stores. In accident cases where the child has eaten just before the injury, it is best to delay anesthesia if possible 4-5 hours to decrease the danger of aspiration of stomach contents. If immediate surgery is necessary, gastric lavage and endotracheal intubation with inhalation anesthesia are indicated.

Premedication

Sedation is a valuable asset in handling the pediatric patient. Nembutal is a satisfactory barbiturate. Morphine and scopolamine are used in combination to produce a good degree of mental sedation, with reduction of mucous secretions, and a high level of analgesia. Demerol may be used in those cases where there is a known history of morphine sensitivity. Nembutal is administered orally or, if more convenient, the dose may be doubled and given rectally. For optimum effect the morphine and scopolamine are given subcutaneously 1 hour before operation. If necessary they may be given intramuscularly half an hour before operation or intravenously for an immediate effect.

A scale of recommended dosages for children, based on the average requirements for weight and age, is given in Table 25.

TABLE 25

PREMEDICATION

(Schedule Used at The Montreal Children's Hospital)

AGE	WEIGHT (KG)	NEM-BUTAL (MG) ORAL 1½ HR PREOP	MOR-PHINE (MG) 1 HR PREOP	SCO-POL-AMINE (MG) 1 HR PREOP
0-6 mo	3-7	~	~	0.10
6-12 mo	7-9	7.5	0.50	0.10
11-18 mo	9-11	7.5	0.55	0.10
18 mo - 2 yr	11-12	15	0.70	0.14
2-3 yr	12-14	15	1.00	0.14
3-5 yr	14-18	30	1.25	0.14
5-8 yr	18-25	30	1.65	0.21
8-10 yr	25-29	50	2.50	0.21
10-12 yr	29-36	65	5.00	0.32
12-14 yr	36-41	80	8.00	0.43

If it is wished to administer the Nembutal rectally the dosage may be doubled.

Anesthesia

Some form of general anesthesia is most satisfactory in pediatric surgery, but the risks involved must be thoroughly understood. The small size of the patient is a technical disadvantage. The respiratory apparatus is not as well developed, and respiratory ventilation is not as efficient as in the adult. The small child does not tolerate as severe a degree of anoxia. Local anesthesia is a definite hazard in any major surgery as there is no control of the child's reactions and the child must be restrained forcibly. Spinal anesthesia, like local anesthesia, is unsatisfactory and requires very heavy sedation to control the child's apprehension.

Rectal administration of Avertin or Pentothal may be used to produce basal anesthesia. In general, however, this route does not give as certain control of the agent as does the inhalation method. It can be used to very good effect in the child who is excessively apprehensive or has been upset by a previous anesthetic experience. In children, inhalation agents are more easily controlled than intravenous agents and present less trouble in their administration. Open drop ether is the safest method and is considered advisable for those

who have only occasional experience in pediatric anesthesia. Endotracheal intubation has proved a very valuable adjunct for intrathoracic and intracranial procedures when administered by those with experience. However, the risks of endotracheal intubation must be kept in mind, i.e., hoarseness and laryngeal edema, laryngospasm, obstruction of the tube by kinking or secretions during operation, and unilateral intubation of a major bronchus. Temperature should be controlled during operation. Normal or just slightly below normal temperatures should be maintained for routine procedures. The young infant and premature child tolerate a slight cooling very well. More profound hypothermia has a use in some of the complicated cardiac and neurologic surgical procedures. During operation body temperature is best observed with a thermocouple placed in the rectum.

Fluid Replacement

Children, in particular infants, require close supervision of their normal fluid balance and the replacement of any deficits that occur. The margin of safety is much smaller in the child than in the adult for several reasons. Febrile reaction to comparatively minor insults is much more marked. The loss of fluids and electrolytes in diarrhea and vomiting can be fatal. Technically, the child presents a more difficult problem in the replacement and control of fluid balance. Normal requirements and deficits must be calculated and the deficits carefully replaced as overloading is as dangerous as inadequate hydration.

The normal daily requirements are calculated on the basis of age and weight and do not follow a straight line relationship. There is a gradual decrease in fluid requirements with age, and for children weighing over 45 kg, adult calculations are used.

TABLE 26
GENERAL REQUIREMENTS OF FLUID THERAPY
IN 24 HOURS

Fluid	100-300 ml/kg 100 ml/kg (newborn infant) 70 ml/kg (premature infant) 70-100 ml/kg (over 20 kg weight)
Saline	20 ml/kg (under 20 kg) 10 ml/kg (over 20 kg)
Blood	20 ml/kg

Milliliters per 24 hrs

Fig 379—Basic daily requirements of fluid replacement in children (After Gross)

Normal saline (0.9%)	155			155	
1/2 M Na lactate	167				167
Darrow's solution	122	35		105	52
Ringer's solution	155	3	3	161	
Ringer's lactate	130	4	4	111	27
1 M KCl		1,000		1,000	
5% NaCl	510			510	
1/2 Solution	159			103	56
1/2 1/2 Solution	80			52	28
Solution for alkalosis	125	30		155	(160 ml. 5% glucose in water, 810 ml. 0.9% NaCl, 30 ml. 1 M KCl to make 1 L.)

Oral Fluids

Orange juice
Milk

4 48 6
27 41 59 28

mEq Values

1 Gm KCl—13.1 mEq of K or Cl
1 Gm NaCl—17.1 mEq of Na or Cl
1 Gm NaHCO₃—11.9 mEq of Na or HCO₃
1 Gm Na lactate—8.9 mEq of Na or lactate
1 Gm CaCl₂—18 mEq of Ca (361 mg. of Ca)
1 Gm Ca gluconate—1.4 mEq of Ca (89 mg. of Ca)
1 Gm Ca lactate—6.1 mEq of Ca (130 mg. of Ca)

$$\text{mEq/L} = \frac{10 \times \text{mg}/100 \text{ ml} \times \text{valence}}{\text{Atomic wt (or molecular wt)}}$$

Transfusion requirements

Whole blood 10-20 ml/kg
Packed cells 10-20 ml/kg
Plasma 10-20 ml/kg
Exchange transfusion 65 ml/kg

The figures in Table 26 are maintenance requirements. Additional fluids and electrolytes must be given to replace losses due to intestinal drainage or suction, excessive perspiration, and increased loss due to fever. To arrive at a satisfactory assessment of fluid balance, a careful record must be kept of the normal fluid loss and of abnormal losses such as result from increased drainage. The child must be assessed clinically at frequent intervals to determine the state of hydration as evidenced by skin turgor, urinary excretion, peripheral edema, fullness of the fontanelles, and evidence of cerebral and pulmonary edema.

TABLE 28
PARENTERAL FLUID THERAPY

Daily Maintenance Requirements (ml/Kg)				
Under 1 mo	1-6 mo	6 mo-2 yr	2-4 yr	10 yr
110	110	100	90	70
<i>Composition of Body Fluids</i>				
Total body water	70% of body wt			
Extracellular fluid				
Infants	25-30% of body wt			
Adults	20% of body wt			
Plasma volume	5% of body wt			
Intracellular fluid	45% of body wt			

Calculation of Fluid Losses
Average Figures Only

Insensible water loss	40 ml/kg/24 hr
Urine loss	40 ml/kg/24 hr
Gastrointestinal loss	30 ml/kg/24 hr

Infants

Mild dehydration	5% loss body wt.
Moderate dehydration	10% loss body wt
Severe dehydration	15-20% loss body wt

Calculation of Rate of IV Flow

$$\text{Drops/minute} \times 4 = \text{ml/hour (approx)}$$

(If shock is present, two-thirds of total 24 hour requirement may be given in the first 12 hours initially at 30-40 drops/minute)

Guide to IV. Potassium Therapy
Average Requirements (mEq)

Mild depletion.	1 mEq/24 hr
Moderate depletion	2 mEq/24 hr
Severe depletion	3 mEq/24 hr.

(Do not use solutions with concentration of K exceeding 3.5 mEq/100 ml)

Guide to 1/6 M Na Lactate Requirements in Severe Acidosis
(e.g., CO_2 less than 10 mEq)

42 ml of 1/6 M Na Lactate/kg body wt will raise the CO_2 combining power approximately 1 mEq/L.

(This is a crude calculation, included here as a safety measure. Usually no more than two-thirds of the calculated requirement should be given in a 24-hour period.)

Severe problems of electrolyte imbalance must be followed by chemical determinations which will guide the course of replacement.

Children in a normal state of balance will tolerate many procedures without added fluid therapy. The newborn infant has adequate fluid reserves for the first 48 hours of life. The premature infant does not require as much fluid therapy as a normal infant. In fact, after surgery it is safer to keep the premature and young infant in a slight degree of dehydration than incur the risks of overhydration. Long-term intravenous therapy poses the problem of caloric and protein balance. Blood, plasma or human albumin, and protein hydrolysates must then be considered as a source to help maintain homeostasis.

Techniques of Fluid Replacement

Hypodermoclysis.—This route is used to give small amounts of 5% glucose in normal saline. Up to 30 ml/kg may be given. Hyaluronidase (1 ml.) given with the infusion will increase the rate of absorption. The infusion is given by placing a needle in the subcutaneous tissues over the scapulae, the pectoral muscles, or the thighs. The disadvantages of this method are that the volume and type of fluid is definitely limited, and there is the possibility of local overhydration and ischemia.

Venoclysis.—This is the most satisfactory route of fluid replacement. Scalp veins can be used as a site of injection. With careful management these veins will serve satisfactorily for short-term therapy. In situations where therapy is to be prolonged, or must be rapid, or certain as in major surgical procedures, fluid is given through a polyethylene catheter tied into the long saphenous vein at the ankle or a vein in the antecubital fossa. In older children superficial veins in the legs or arms are of sufficient size to insert a needle directly.

Postoperative Care

Aspiration of secretions or vomitus is a very real hazard in the postoperative child. Careful attention must be paid to the posturing of the patient. Continuous or intermittent gastric suc-

A

B

Fig 381—A, Type of restraint jacket which is tied to the bed. The arms are splinted at the elbows, but there is considerable freedom allowed. The leg is immobilized with a padded splint.

B, Glove hitch with a single tie over the padded extremity as a form of restraint for children.

tion may be necessary. A Levin tube may be introduced into the stomach or a catheter introduced at frequent intervals. Endotracheal suction is sometimes required. *Constant nursing supervision is a necessity*

The infant also requires an atmosphere controlled for temperature, humidity, and oxygen. This is best facilitated by the use of the Isolette. It has the added advantages of an isolation technique, and the child may be exposed for constant observation and daily weight estimation. Nasal oxygen should be avoided in small children because of the danger of gastric distention. Older children requiring oxygen or humidity may be placed in oxyhumidity hoods

When the limbs must be tied down, a non-constricting, padded clove-hitch knot with an added single tie should be used. *Padded splints are used to restrain the arm or leg for intravenous therapy.*

Clear fluids should always be offered as the first postoperative feeding, and in nonintestinal cases these are started within 4-8 hours. In infants, when such fluids are tolerated, they are alternated with skim milk, and feedings progress to formula and diet for age. Older children graduate to a normal diet as tolerated. Gavage feeding is used in infants that are too weak to suck but will tolerate alimentary feedings. Older children may require tube feeding

Fig. 382—Modified Murphy drip apparatus for gastrostomy or jejunostomy feedings.

Dressings should not be cumbersome or constricting. In most instances they can be dispensed with shortly after operation. The problem of soiling of wounds can be dealt with more efficiently if the wound is exposed, cleansed, and dried as necessary. Restraints may be required to prevent the child from damaging a surgical repair or disrupting intravenous therapy. Mild restraints, such as a jacket which can be tied to the bed or one in which the sleeves are splinted, are sufficient in some cases

as a means of ensuring an adequate intake. Gastrostomy or jejunostomy is indicated in the postoperative care of certain surgical conditions of the esophagus, stomach, and duodenum. These are administered slowly by means of a continuous drip. If the gastrointestinal tract is overloaded, the apparatus allows regurgitation to occur into an open Murphy drip chamber rather than up the proximal esophagus. Daily vitamin requirements are given by oral or intravenous route.

HEAD AND NECK

The majority of the conditions in the head and neck have been discussed in Chapters 10 and 12

CONDITIONS FOUND IN CHILDHOOD

Congenital anomalies

- 1 Choanal atresia
- 2 Cleft lip and palate
- 3 Micrognathus
- 4 Branchial cleft cyst and sinus
- 5 Midline cervical cleft
- 6 Fistula auris congenita

Choanal Atresia.—In this congenital anomaly the posterior nares remain closed. The infant is unable to breathe through the nose, and because of this respiratory obstruction, bottle or breast feeding is impossible. If the posterior nares are only narrowed, a small catheter is passed through the nose into the posterior nasopharynx to ensure a clear airway. In complete obstruction a tracheostomy is required. The child can then be maintained to an older age, when a definitive plastic repair of the posterior nares can be performed.

Micrognathus.—Micrognathus or retrusion of the mandible can be a hazard of the newborn infant. The mandible is underdeveloped, and the chin is markedly recessed. As a result, the pharynx is reduced in size and the tongue causes obstruction of the airway. Immediate treatment consists of pulling the tongue forward and posturing the child with the head in the hyperextended position. The tongue can then be fixed in a forward position by sutures through the chin. Aggravated cases require a tracheostomy. Once a clear airway has been ensured, plastic procedures can be considered at a later date to correct the deformity of the mandible.

Midline Cervical Sinus.—This represents an abnormality in the junction of the branchial arches in the midline anteriorly. It presents as

Fig. 383.—Midline cervical sinus showing the vertical fusion defect.

a weeping, vertical cleft and may extend from the suprasternal notch to the level of the hyoid bone. It must be differentiated from sinuses of the branchial clefts which are situated laterally, and from midline sinuses communicating with thyroglossal duct cysts. Treatment is excision, and the best cosmetic result is obtained with a Z-plasty incision.

THORAX

The Breast

Congenital anomalies are rare and have been discussed elsewhere (see Chapter 14). The common condition in infancy is that of breast abscess formation in the neonatal period. The infant breast responds to the hormonal stimulation of the mother, hypertrophies, and becomes engorged during the first 2 weeks of life. This state normally subsides, but a staphylococcal infection with abscess formation may occur during this period and may be localized to the breast or spread to the pectoral fascial planes and the anterior pectoral nodes. Treatment consists of warm saline compresses, antibiotics, and drainage when the abscess localizes. A radial incision is made over the localization adjacent to the nipple. This leaves a minimal scar and does not interfere with later breast development and continuity of the ducts.

Anomalies of the Thoracic Cage

These are encountered in infancy and childhood. Isolated anomalies of the ribs are usu-

Fig 384—Breast abscess in the newborn period

ally insignificant, although the presence of a cervical rib may become a problem in the adult. Pseudarthrosis of the first rib may be found on radiologic examination and must not be confused with a possible fracture.

Complete or partial defects of the sternum allow herniation of the heart and abdominal contents, a condition known as *ectopia cordis*. Major defects of this nature are usually associated with marked cardiac anomalies. Plastic procedures have been devised for the correction of the anomaly.

The thoracic cage may develop abnormally to produce a deformity in which the sternum is displaced either dorsally or ventrally. The etiology is obscure, but the condition is congenital, familial, and progressive. Dorsal displacement of the sternum, most marked in the lower portion, associated with prominence of the costochondral junction and indrawing of the costal cartilages is known as *pectus excavatum* or *funnel chest*. The reverse deformity, with ventral displacement of the lower portion of the sternum and a deep bilateral sulcus of the costal cartilages, is known as *pectus carinatum* or *pigeon breast*. These deformities can be corrected by reconstruction of the anterior thoracic cage. Treatment in infancy is a minor procedure. If delayed, treatment should wait until the thoracic cage is stabilized. This is done by several methods

Pectus Excavatum.—

Infants Under One Year.—

1. Retrosternal division of the attachment of the diaphragm
2. Wire traction of the sternum with or without osteotomy

Children Over 5 Years.—

1. Wedge resection of the costal cartilages with osteotomy and elevation of the sternum
2. Subperichondral resection of the deformed costal cartilages and elevation of the sternum

Indications for Surgery.—

1. Cosmetic
2. Psychic

3. Rapid progression of the deformity
4. Cardiac compression, paroxysmal auricular tachycardia, and recurrent pulmonary infection

Satisfactory results are more consistently found with the more radical types of procedure and after the ribs have become fixed

Pectus Carinatum.—This is not as common a lesion but will respond to a similar type of surgical approach if indicated

Fig 386—X-ray of pectus excavatum showing the posterior deformity and angulation of the lower sternum. Barium outlines the deformity at the skin

Larynx, Trachea, and Bronchi

The branches of the pulmonary tree are involved in a variety of conditions, the importance of which is due to possible obstruction to the free passage of air or the accumulation of secretions. Obstruction may be congenital, or due to tumor growth and may occur within the airway proper or by compression from without. The most frequently encountered anomaly is *tracheo-esophageal fistula* which is usually associated with *esophageal atresia* and will be discussed with the anomalies of the esophagus

Laryngeal stenosis is an anomaly which can cause obstruction of the airway due to a definite narrowing of the lumen at the level of the vocal cords. It causes a marked inspiratory

stridor. These children must be carried on prophylactic tracheostomy to ensure an adequate airway until the larynx has grown sufficient size that a plastic repair may be carried out. Narrowing of the trachea and bronchi is rare. Abnormalities in the distribution of the bronchi are usually associated with agenesis of the adjoining areas of lung. Infants may show a condition known as *laryngo-tracheomalacia* in which the normal rigidity of the trachea has not yet developed. Radiologic examination of these infants may give the impression that there is a narrowing of the trachea. Fluoroscopic examination will show an inspiratory collapse of the trachea and not a fixed narrowing of the larynx and trachea

Congenital anomalies outside the trachea, such as vascular rings, or aberrant vessels must also be considered as causes of tracheal compression (See Chapter 16)

Following are the two common causes of tracheal obstruction in childhood:

Acute Laryngotracheobronchitis.—This is an acute infection which is sudden in onset and may progress rapidly to complete respiratory obstruction. Clinically it is known as *croup* because of the characteristic inspiratory crowing with indrawing of the suprasternal areas and the lower costal margin. There is marked edema of the larynx and accumulation of secretions in the obstructed trachea and bronchi. Tracheostomy, when indicated, must be supported by antibiotics, oxygen, and high humidity.

Aspiration of Foreign Bodies.—Children are very prone to the aspiration of foreign bodies into the trachea and major bronchi. These may be small objects that are picked up and carried in the mouth, or they may be solid forms of food. The common offenders are peanuts and pieces of carrot. There may be distress at the initial time of the accident, and then the child may be comparatively symptom-free. X-ray examination will show the specific foreign body if it is radiopaque. If it is not radiopaque, the diagnostic sign may be the *emphysema* that develops in the affected portion of lung due to a ball-valve type of obstruction in a major bronchus. Bronchoscopic examination for diagnosis and removal of the foreign body, if present, is indicated. If the

Fig 387—Staphylococcal pneumonia in infancy

A, Bronchopneumonia of the left lung with empyema

B, Pyopneumothorax 24 hours later

C, Closed intercostal drainage established with expansion of the lung and drainage of the empyema

foreign body is unrecognized, the late complications of pulmonary collapse, abscess formation, and bronchiectasis will occur.

Lungs

Congenital lesions vary from abnormalities of lobar segmentation to complete agenesis of one lung or partial agenesis of various lobes. In unilateral agenesis there is overexpansion of the normal lung with marked displacement of the mediastinum and heart. The degree of embarrassment of the venous return to the heart and respiratory exchange may be fatal. Isolated or multiple *congenital cysts* may occur, and these represent abnormal formation in the lungs. Some may communicate with a bronchus, and if there is a flap-valve mechanism present, they may expand to enormous size.

Mucoviscidosis is a congenital defect in the enzyme mechanism of the mucus-secreting glands. The bronchial secretions are thick and tenacious and accumulate in the pulmonary tree. As a result these children are subject to repeated bouts of respiratory infections and usually succumb to a final attack of pneumonia.

Congenital atelectasis is seen in the newborn infant. Areas of lung may fail to expand due to obstruction by secretions or aspiration of fluids during birth. Careful suctioning of the trachea after birth will prevent this complication. If left untreated pneumonia will ensue.

Pneumothorax is seen as a spontaneous result of the rupture of a pleural bleb from interstitial emphysema, or may be the result of overenthusiastic resuscitation. If respiratory distress indicates an expanding pneumothorax, it must be aspirated immediately. Persistent tension pneumothorax must be controlled by an intercostal catheter connected to an underwater drainage system.

Acute Infection of the Lungs and Pleura.—Infants are very susceptible to staphylococcal infection of these tissues. The pathologic process is one of bronchopneumonia and or septicemia, with the formation of localized abscesses throughout the parenchyma. The onset and progress of the disease may be very rapid and dramatic. Infection may dominate the picture, with evidence of septicemia. Pleural

effusion may occur as a reaction to the underlying lung infection, and if this effusion becomes infected, an empyema develops. Rupture of an abscess through the pleura allows the formation of a bronchopleural fistula and a pyopneumothorax. The accumulation of air may lead to a tension pyopneumothorax. Here the mechanical upset in the function of the mediastinal structures rather than the infection may kill the child. These children must be treated strenuously with antibiotics and watched for the sudden onset of increasing pulse rate, dyspnea, and cyanosis which indicate possible development of tension pyopneumothorax. This must be confirmed by immediate x-ray examination. A pyopneumothorax must be controlled by intercostal drainage to an underwater seal (See Fig. 224). Any infant with an empyema should have a thoracentesis. If smear of the fluid demonstrates the presence of gram-positive cocci, a prophylactic intercostal drainage should be performed. This is a safeguard against the development of a tension pyopneumothorax and also allows the drainage of infected material from the pleural space. Loculated areas of pus may develop as a later complication. As the lung is then adherent to the thoracic cage, local aspiration is effective. In the infant it is seldom necessary to do an open drainage of the chest. Another late complication may be the development of large bullae or pneumatoceles which must be followed carefully by frequent radiologic studies; these usually subside.

GASTROINTESTINAL SURGERY

ESOPHAGUS

Introduction

While the general principles of abdominal surgery provide the basis for the definitive corrective procedures carried out on the gastrointestinal tract in infants and children, it should be pointed out that meticulous attention must be given to the supportive therapy in the preoperative, operative, and postoperative care of these patients. The three principles of early diagnosis, adequate supportive therapy through out, and the application of planned and carefully carried out corrective surgical procedures play an important role in the lowering of

morbidity and mortality. The associated anomalies that may appear as complications of the presenting condition must be sought, and as most of these conditions are only relative emergencies, the time taken to obtain a comprehensive preoperative picture in any infant is well worth while. On the list of acute abdominal emergencies admitted to the surgical service of a children's hospital, the irreducible inguinal hernia takes first position and is followed by cases of acute appendicitis and intussusception.

Congenital Atresia of the Esophagus With and Without Tracheo-esophageal Fistula

The Anomaly.—In the 4-5 mm. human embryo, the esophagus first appears as a short

canalization, accompanied by its elongation, gives rise to the normal esophagus which joins hypopharynx to the stomach. Arrest in development or aberration from a normal development gives rise to five anomalies in this region and four of these five types have as the prime anomaly an atresia of the esophagus. The first and most common is one in which there is a blind upper esophageal pouch and a fistula between the distal esophageal segment and the posterior aspect of the trachea, usually just above the carina. This type of anomaly is present in about 88% of cases. The second type, which occurs in about 5% of cases, comprises a blind upper esophageal pouch and a blind lower esophageal segment without a tracheo-esophageal fistula being present. In about 3% of cases there is a congenital fistula

Fig. 388.—Congenital atresia of the esophagus with or without tracheo-esophageal fistula

ring of tissue which separates the hypopharynx from the stomach, and prior to its elongation, the developing trachea and esophagus comprise a single lumen tube. This single lumen becomes divided into two lumina by the ingrowth of two lateral septa which fuse to form the trachea ventrally and the esophagus dorsally. The last part of the septum to be fused is the most caudad portion in the region of the carina. Conversion of the esophagus to a solid rod of cells and its subsequent re-

between the esophagus and the trachea, but no esophageal atresia is present. The remaining two types, which are exceptionally rare, are, first, an upper esophageal component that communicates with the posterior aspect of the trachea and is accompanied by a blind lower esophageal pouch, and, second, an upper and lower esophageal segment that communicate with the posterior aspect of the trachea.

Complicating Factors.—Many of these infants are premature, and this appears to be

a serious complication to satisfactory treatment. Many of these infants have major associated congenital anomalies of the heart, the gastrointestinal system, the genitourinary tract, and the central nervous system. Delay in the diagnosis and persistent attempts at feeding these infants give rise to pulmonary complications. Aspiration pneumonia, characteristically located in the right upper lobe, is the common finding. If a fistula is present between the lower esophageal segment and the posterior aspect of the trachea, the regurgitation of acid chyme into the tracheobronchial tree gives rise to a very formidable type of pneumonic process.

aroused, an attempt to pass a nasogastric tube should be made. One must be aware of the possibility that the catheter which has been introduced into the blind upper pouch may curl on itself and give the impression that it has entered the stomach. The confirmation of the diagnosis is obtained by the injection of less than 1 ml of Lipiodol down the catheter and the visualization under fluoroscopy of the blind upper pouch. The intestinal tract should be carefully visualized for the presence of gas within its lumen, and if none is present no fistula exists between the trachea and the distal esophagus. However, the diagnosis of a tracheo-esophageal fistula *without* esophageal

FIG. 389.—Esophageal atresia with tracheo-esophageal fistula. X-ray examination with radiopaque medium filling the proximal blind pouch of esophagus. Gas in the abdomen indicates that there is a communicating fistula between the trachea and lower esophagus. There is evidence of atelectasis in the right upper lobe (arrows).

Diagnosis.—This should be relatively simple to make if the condition is kept in mind. In the newborn infant the presence of excessive salivation and the inability to take feedings should immediately suggest the possibility of this defect. Once the suspicion has been

atresia is one that is fraught with difficulties and indeed may not be made before operative intervention reveals the fistula. In some cases the tracheo-esophageal fistula will be evident when Lipiodol is put down the lumen of the esophagus and appears in the tracheobronchial

tree. In other cases, one may have to resort to bronchoscopy in order to establish a diagnosis, and this may be facilitated by the placing of methylene blue in the esophagus, which may be seen to appear in the trachea.

Treatment.—The early diagnosis of the condition as outlined is of prime importance. The infant should be transported in a semi-upright position, which facilitates the removal of the excess saliva from the blind upper pouch and tends to diminish the amount of regurgitation of acid chyme into the tracheo-bronchial tree. While early definitive treatment is important, a few hours' delay to give adequate supportive preoperative care and initiate therapy for the pneumonic process which may be present is time well spent. The greatest advance has been the acceptance of the fact that the continuity of the esophagus should be established and the fistula, if present, tied off in a one-stage operation. The surgical procedure of choice is a right-sided thoracotomy through the 4th interspace and a transpleural approach to the esophagus. The azygos vein is isolated and cut between ligatures. The mediastinal pleura is incised longitudinally, and the upper esophageal pouch is then isolated and dissected free as far cephalad as possible. There is little reason for concern about the blood supply of this proximal segment. The tracheo-esophageal fistula is then identified, clamped, and amputated with an adequate cuff on the tracheal side to allow closure. End-to-end anastomosis of the esophageal segments may be accomplished at this time, but the greatest problem at this stage is the distance separating the two segments of esophagus. Every effort must be made to effect an anastomosis without tension. If the lower esophageal segment appears to be short and extensive dissection is required, it is better to bring the stomach up into the thorax to assure a tension-free anastomosis, and if the precarious blood supply to the lower esophageal segment appears to be inadequate, then primary anastomosis between the upper esophageal segment and the stomach may be indicated. Two methods of anastomosis are recognized. The method proposed by Haight is an end-to-end anastomosis, where all layers of the distal segments are sutured to the mucosa of the upper segment, and the cuff of

muscularis of the upper segment is brought down to cover this anastomotic line. The other method is an end-to-end anastomosis using a single layer of interrupted fine black silk sutures, each stitch of which includes all layers of both segments.

Postoperative Care.—Early postoperative feeding of these infants is of prime importance, and this may be carried out by means of a gastrostomy feeding regime. The gastrostomy may be instituted at the time of the primary operative procedure or done under local anesthesia 24-48 hours later. The gastrostomy serves a dual purpose, for in many of these infants where postoperative esophageal stricture occurs, a retrograde bouginage can be carried out through the gastrostomy on an outpatient basis without anesthesia. Systemic antibiotics should be administered and periodic posterior pharyngeal suction carried out. Gastrostomy feedings can be started in 48 hours. As posterior pharyngeal suction produces less and less, and it is obvious that the infant is swallowing saliva, oral feedings may be undertaken at about the 10th postoperative day when the restitution to integrity of the esophageal segments has been accomplished. At about 3 weeks the esophagus should be examined with Lipiodol and preventive or corrective measures taken to eliminate any serious esophageal stricture at the site of the anastomosis, if this is demonstrated. Periodic follow-up examinations should be carried out for the first 6 months of life, and then at less frequent intervals thereafter. The general principles of therapy in the patient with esophageal atresia with tracheo-esophageal fistula apply to the other anomalies of the esophagus.

Results of Therapy.—The results of therapy would seem to depend primarily on the rapidity with which a diagnosis is made and the precautionary care given before the arrival of the infant for surgery. Prematurity, which occurs in about one in four of these infants, presents a formidable challenge and is accompanied by a high mortality rate; it is a possible indication for a staged procedure. The severe associated congenital anomalies play their role in raising the mortality statistics. In competent hands, it would appear that the mortality rate, including all complicating fac-

from left to right and a palpable pyloric mass which is most readily felt in the right upper quadrant at the lateral border of the rectus. Where there has been great dilatation and hypertrophy of the stomach itself, the tumor mass may be felt lower down on the right lateral side of the abdomen. In unusual or atypical cases, confirmation of the diagnosis may be obtained by the use of a barium swallow, during which a persistently stenosed and elongated pyloric canal is visualized. Nutritional edema is not present in these cases

Fig 391.—Congenital hypertrophic pyloric stenosis. Barium meal outlines the narrowed pyloric canal (arrows). The pyloric tumor projects into the duodenum causing a mushroomlike cap.

Differential Diagnosis—Pyloric stenosis must be differentiated from pylorospasm in which the symptoms vary from day to day, and relief is obtained by the administration of phenobarbital and atropine. Other types of intestinal obstruction of congenital origin usually give rise to vomiting in the first or second day of life and these can be differentiated from pyloric stenosis where vomiting rarely occurs before the first week or 10 days of life. In the intestinal obstructions related to malrotation of the gut, with volvulus or the presence of peritoneal bands, the vomitus usually contains bile. Poor feeding patterns instituted by the parent can produce vomiting which usually responds to correction in the feeding regime.

Preoperative Care.—While the performance of a pyloromyotomy is of prime importance in the correction of this condition, the preoperative preparation of the patient for surgery must be dealt with carefully. This condition is rarely a surgical emergency, and, indeed, the more precarious the baby's condition, the longer the operation should be delayed. Replacement of fluid by intravenous therapy, in particular the administration of chloride and potassium, must take precedence over the operative procedure. Blood transfusion preoperatively is rarely needed, but where the hemoglobin is low or the plasma proteins appear to be decreased, blood or plasma may be given in the amounts of 20 ml./kg. body weight. Feedings may be continued during the preoperative period but should consist mainly of clear fluids comprising glucose, water, and normal saline. Adequate wound healing is sometimes a problem in these debilitated infants, and the administration of large doses of vitamin C and the correction of low plasma protein levels should be encouraged.

Operation.—The surgical approach to the hypertrophied pylorus may be either through (1) a right upper rectus-splitting incision or (2) a transverse subcostal incision. The latter is preferred. The subcostal incision is made one fingerbreadth below the right costal margin and deepened so that the transversus abdominis muscle and peritoneum are entered as one layer. The opening and closing of the peritoneal cavity are facilitated by making the incision over the liver. The liver is retracted upward and the pylorus delivered through the incision. The blood supply to the pylorus is seen to come from the upper and lower surfaces, and an avascular area between the termination of these two blood supplies is chosen for the incision. One third of the muscle mass is incised with a scalpel in the long axis of the pylorus, then by means of a hemostat the circular muscle fibers are widely separated until the submucosa bulges to the level of the serosa. The utmost care must be taken in the separation of these muscle fibers distally to avoid penetration into the duodenum, and an adequate incision must be made on the antrum of the stomach if uniformly good postoperative results are to be obtained. There is usually

little trouble with bleeding, and after the pylorus has been replaced in the peritoneal cavity the stomach is swept up into the left upper quadrant of the abdomen. In these malnourished infants healing is poor and closure of the abdomen must be meticulously accomplished.

Postoperative Care.—In most cases feeding may be begun 4-6 hours postoperatively, and

the first few offered feedings should be glucose and water. When these are tolerated, the appropriate formula can be administered, and the only important qualification is that it should not be offered in large amounts. Small, frequent feedings are better tolerated for the first few days, and continuation of intravenous therapy should be carried out until adequate amounts of formula are being taken by mouth

Fig 392.—Fredet Rammstedt operation for hypertrophic pyloric stenosis

DUODENUM AND SMALL INTESTINE

Congenital Atresia of the Intestinal Tract

This includes atretic areas from the first portion of the duodenum, through the jejunum and ileum, and on into the colon. Atresia, by definition, is the absence of a lumen. This may take the form of an internal diaphragm, or there may be discontinuity of the bowel with the proximal portion ending in a blind sac. The accepted embryologic theory for the development of these atretic areas is that during the 2nd or 3rd month of intrauterine life a failure of recanalization of the rapidly proliferating epithelium occurs and gives rise to an atresia. However, if recanalization takes place and there is a residual narrowing of the lumen, congenital stenosis is the result. Atresia may occur singly in the intestinal tract or in

conjunction with other atretic areas elsewhere. The ileum is the most common site for this abnormality of development, with the duodenum in second place. Ileal atresia is twice as common as duodenal atresia, and duodenal is about twice as common as jejunal atresia. The isolated colonic atresia is an extremely rare lesion. The gross picture of the intestinal tract in atresia is a striking one. Proximal to the level of obstruction the bowel is greatly dilated and may measure 4-5 cm. in diameter, whereas distal to the obstruction the bowel may measure 1 cm. in diameter. With the distention of the proximal portion of the intestinal tract there is concomitant thinning of the bowel wall, and marked ischemia may be present. Indeed, perforation often occurs. Associated with atresia of the small intestine there is always present an "unused colon,"

Fig 393

Fig 393—Duodenal atresia. Plain film of the abdomen showing marked distention of the stomach and duodenum and no gas in the distal bowel.

Fig 394

Fig 394—Ileal atresia. Plain film of the abdomen showing distended loops of proximal bowel and no gas in the distal colon or rectum.

which has been designated by some as a micro-colon. This distal colon, however, is normal in all respects and may be dilated to normal size and function with little difficulty. The absence of stratified squamous epithelial cells in the meconium of a newborn baby (Farber's test) is a diagnostic aid in cases of intestinal atresia, that is, the ingested vernix caseosa which is suspended in the amniotic fluid cannot pass an atretic area in the intestinal tract. While it is true that obstructions of the large bowel are better tolerated than those of the small bowel and those of the low small bowel better than those of high small bowel, nevertheless all these babies will show symptoms on the first day of life since this intrinsic obstruction of the intestinal tract has been present for such a long period of time. With the exception of the rare atresia of the duodenum which is proximal to the entrance of the ampulla of Vater, the vomiting of all these infants will be bile-stained, and this finding is one of the signs that necessitate the utmost urgency in diagnosis and treatment. The gross appearance of the meconium in these infants may be misleading, and the amount of abdominal distention present may depend on the level of the atresia and the adequacy of the decompression of the proximal bowel by the vomiting. Diagnosis may be confirmed by x-ray examination of the abdomen and the ingestion of radiopaque material. Barium is not recommended because of the dangers of regurgitation and aspiration and the inspissation of the barium in the intestinal tract. However, an enema in these infants, using Lipiodol, is of benefit in that a malrotation of the bowel can be ruled out and the presence of an "unused colon" visualized.

Choice of Operative Procedure.—A long right rectus incision centered on the umbilicus is best, since it gives ready access to the whole gastrointestinal tract. For the atretic area which is diaphragmatic in nature, excision of the segment of bowel containing the diaphragm, with anastomosis, is the procedure of choice. If this is difficult, an enterointerostomy should be performed to circumvent the obstruction. For the duodenal atresia below the ampulla of Vater and for upper jejunal atresias, duodenoduodenostomy is recommended. Gastrojejunostomy should be avoided and is perhaps indi-

cated only in those lesions that are above the level of the ampulla of Vater. For the other atretic areas in the intestinal tract, three approaches may be considered: (1) a long side-to-side isoperistaltic anastomosis, (2) a double-barreled Mickulicz type of enterostomy, which after 4-5 days may have the spur crushed with a specially designed crushing clamp, or (3) an end-to-end anastomosis, where possible, after decompression of the proximally distended loop and excision of 4-5" of the most dilated and atonic portion of the proximal bowel and distention of the distal collapsed portion of the intestine with normal saline solution, air, or mineral oil. A one-layered anastomosis of interrupted Connell type sutures with No 5-0 silk on an atraumatic needle is preferred.

Congenital Stenosis of the Intestinal Tract

While the embryology of a congenital stenosis of the intestinal tract is similar to that of an atresia, as mentioned above, stenosis is in fact a separate entity. In this connection, the stenoses of the duodenum are twice as common as those of the ileum. As in the case of an intestinal atresia, an isolated stenotic area in the colon is rare, and multiple areas of stenosis in the intestinal tract are also not commonly found. There is a compromise to the lumen of the intestine. A diaphragm or tissue may remain in which there is a small perforation that measures 2-3 mm. in diameter. In other cases the aperture may be larger, and there may be only slight compromise to the lumen. Proximal to each area of narrowing there is dilatation of the bowel, and if the obstruction is of sufficient duration there may be hypertrophy as well. If the lumen is extremely narrowed dilatation is great, but in contradistinction to atresia, perforation of the intestine occurs uncommonly proximal to the stenotic area. The age of onset of symptoms varies with the severity of the stenosis and, when severe, may occur in the first week of life. In the marked forms of intestinal stenoses the symptoms may be indistinguishable from those of intestinal atresia, whereas in the milder cases the symptoms may be only occasional vomiting, intermittent abdominal pain,

3 A normally rotated intestine where the cecum and ascending colon are unattached posteriorly and are excessively mobile

Complications which can arise as a result of these arrests in rotation are as follows:

1. Duodenal obstruction
2. Volvulus of the midgut
3. Reversed rotation
4. Internal hernia

Volvulus of the Midgut

With nonrotation of the intestine, a condition exists in which a long portion of the intestinal tract is suspended from a mesentery with an extremely short base. Under these conditions the entire length of the midgut may rotate in a clockwise manner about the axis of the superior mesenteric artery. When the midgut has rotated through two or more

Fig 393—Rotation of the gut.

Duodenal Obstruction

When the cecum lies in close proximity to the duodenum it may be fixed in this position by peritoneal bands which arise in the region of the cecum or ascending colon and insert into the posterior abdominal parietes to the right of and below the third portion of the duodenum. Pressure of the cecum, itself, or of these posterior peritoneal bands, gives rise to duodenal obstruction which is usually high grade but incomplete. Great dilatation of the stomach and proximal duodenum occurs and this is associated with bile-stained vomitus. This condition is easily remedied by cutting the band or freeing the cecum and allowing it to attain a position in the left upper quadrant of the abdomen, where it should be allowed to remain.

right angles about this axis, congenital volvulus exists. The pathologic principles apply here as to volvulus elsewhere. Here we have a closed loop, with the obstruction lying proximally at the region of the duodenojejunal junction and distally somewhere in the region of the middle of the transverse colon. Because the volvulus occurs around the origin of the superior mesenteric artery and vein, venous engorgement, edema, and infarction of the whole of the midgut may be imminent. Volvulus of the midgut gives signs and symptoms of a high small bowel obstruction, with vomitus which is bile-stained, dehydration, and electrolyte imbalance. The amount of abdominal distention is variable. It may be limited to the epigastrium or it may be generalized, depending on whether or not gas has entered

or is forming within the involved loop. Barium enema will show the cecum in the epigastrium or the right upper quadrant of the abdomen, and this, associated with signs and symptoms of a high small bowel obstruction, will give a clue to the diagnosis.

Treatment is laparotomy after adequate preoperative decompression and preparation. The volvulus is reduced and the cecum must be freed and allowed to migrate into the left side of the abdomen. Where gangrenous bowel is present it must be resected and anastomosis accomplished. It is now well known that the newborn infant will tolerate the resection of a large amount of small intestine, and this out in every case. The abdomen is closed in layers and a 1/4" Penrose drain placed in the peritoneal cavity. Meticulous postoperative care is required in these infants, and protracted diarrhea may pose a difficult problem which can usually be overcome with a careful feeding regime and the use of a fat-free formula.

Reversed Rotation

Reversed rotation of the midgut loop may present a puzzling problem for the surgeon who laparotomizes an infant whenever this condition exists. The embryogenesis lies in a return of the postarterial loop of the midgut to the peritoneal cavity before the prearterial loop has entered, and clockwise rotation of 90 degrees allows the colon to come to lie behind the superior mesenteric artery. The duodenum will cross in front of the transverse colon and the superior mesenteric artery. If this anomaly of rotation is associated with an imperforate anus or Hirschsprung's disease, the performance of a transverse loop colostomy may be difficult unless this anomaly is understood.

Internal Hernia

Internal or intra-abdominal hernias may occur at several sites and give rise to intestinal obstruction and may appear in any part of the mesentery. Herniation through a defect in the mesentery in the region of the terminal ileum is the most common variety in childhood. Other sites include those through the ascending mesocolon and the sigmoid meso-

colon and the extremely rare variety which transgresses the foramen of Winslow. Internal hernias seen in infancy and childhood also include the mesentericoparietal types. Hernias of this group are congenital in origin and may arise from a defect in the mesentery or from a defect in fusion of the ascending or descending mesocolon with the posterior abdominal parietes. The paraduodenal variety occurs in the region of the junction of the duodenum and jejunum, where the duodenum emerges from its retroperitoneal position. Two potential fossae are present, one which develops on the left and faces to the right and the other which develops on the right and faces to the left. These have been called, respectively, left and right mesentericoparietal hernias. (See Fig. 378.)

Symptoms and Signs of Intra-abdominal Hernia.—When these intra-abdominal herniations give rise to symptoms they are the same as those associated with intestinal obstruction, i.e., nausea, vomiting, crampy abdominal pain, and dehydration, and where the incarcerated intestine becomes deprived of its blood supply, melena may appear. A palpable mass is sometimes present, and auscultation of the abdomen may reveal high-pitched bowel sounds. Roentgenologic examination of the abdomen will reveal dilated and gas-filled loops of intestine above the site of obstruction, and there may be a sentinel loop. In the mesentericoparietal variety the radiologic picture of the intestinal pattern may be such as to show the small bowel collected into these peritoneal spaces.

Treatment.—The treatment is to release the intestinal obstruction present, reduce the hernia, and repair the defect in the base of the mesentery. Resection of the nonviable intestine is carried out. Reduction of this hernia in the infant is not usually difficult, but it must be remembered that in the left mesentericoparietal hernia the neck of the sac contains the inferior mesenteric artery, while in the right mesentericoparietal hernia the neck of the sac is in close proximity to the superior mesenteric artery. The presence of these two important vascular structures in the vicinity of the hernial neck precludes the random incision of the neck to release the entrapped intestinal contents. Laparotomy is undertaken for the mani-

festations of intestinal obstruction, and the diagnosis of internal hernia, if suspected preoperatively, may be confirmed only at the time of laparotomy. A thorough understanding of the sites and the mechanisms of these hernias that occur in infancy and childhood should be part of the armamentarium of every surgeon who undertakes operation in this age group

Omphalomesenteric Duct Apparatus

Embryology.—In the human embryo, at the beginning of somite formation at about the age of 16 days, the primitive gut lined by

testinal portal and becomes delineated as the foregut. Similarly, at the caudal end of the embryo an entodermally lined sac which comprises the embryologic hindgut remains in communication with the yolk sac through the posterior intestinal portal. When the embryo contains about 14 somites, or is about 22 days of age, there is a region of the primitive gut that lies between the foregut and the hindgut which is destined to be included within the embryo but as yet has no floor and communicates with the yolk sac. This region is known as the embryologic midgut. As the foregut and hindgut increase in length, at the expense of the midgut, the midgut remains in

Fig 396—Varieties of Meckel's diverticulum

entoderm has a large communication with a similarly lined sac which is known as the yolk sac. The first portion of the primitive gut to be incorporated within the body of the embryo is that which lies under the head process, and with the forward growth of the head an entodermally lined tube communicates with the yolk sac through the anterior in-

communication with the yolk sac by a very narrow canal which is known as the yolk stalk or the omphalomesenteric duct. While the yolk sac is spoken of as a vestigial structure, morphologically it is of considerable size in the young embryos, and as the umbilical cord is formed, the yolk stalk is embedded in the substance of the cord, and the

small yolk sac is carried out to be caught between the amnion and the growing placenta. Our concern, then, in the discussion of the omphalomesenteric duct apparatus is not the yolk sac per se as it is extraembryonic but the varieties of form that a partial persistence of the yolk stalk may take. A sacculaton on the antimesenteric border of the ileum represents a partial persistence of the yolk stalk, and is known as a *Meckel's diverticulum* when it ends in a blind pouch.

Fig 397—Patent omphalomesenteric duct. The duct is patent from the umbilicus to the ileum and has prolapsed slightly onto the abdominal wall.

Persistent Omphalomesenteric Duct

The omphalomesenteric duct extends from the primitive yolk sac to the antimesenteric border of the ileum. This duct may fail to obliterate and presents as a fistulous opening in the depression of the navel. It may secrete a thin mucuslike material which causes maceration of the umbilicus. Because of its communication with the ileum, contents of the small intestine may issue from the umbilicus.

Cauterization of the ostium of this fistula is futile, and careful probing or the injection of the fistula with Diodrast or Lipiodol will show the nature of the communication. The treatment of choice is excision with repair of the bowel wall at one end and excision of the fistula from the umbilicus at the other.

Meckel's Diverticulum

Meckel's diverticulum is one of the commonest anomalies of the intestinal tract. It has been stated that it is present in 2% of people, is 2" long, and is found 2' proximal to the ileocecal valve. In some series its incidence is closer to 3% and its length varies from 1/2-3". It may arise from 12-36" proximal to the ileocecal valve. It is not often a source of trouble, but when pathologic changes ensue they are likely to be serious ones. The

Fig 398—Meckel's diverticulum.

mucosa of a Meckel's diverticulum varies greatly in its histologic picture and may include gastric, colonic, or ileal type mucosa, or pancreatic tissue, within its substance. If symptoms arise from a Meckel's diverticulum they are most likely to do so in the first 2 years of life, and fully 50% of patients fall within this age group. The complications include peptic ulceration with perforation or hemorrhage, obstructive symptoms from intussusception or volvulus, and inflammatory symptoms with or without perforation.

premedicated and prepared for the operating room which is in readiness should reduction be impossible

4. That 10-12" of the terminal ileum be visualized at the time of the reduction
5. That cessation of symptoms should follow the hydrostatic reduction

Objections advanced to reduction by barium enema are as follows:

- 1 That it is an unsatisfactory procedure for patients with an ileoileal intussusception
- 2 That it may be incomplete, particularly in those intussusceptions which are ileoileocolic
- 3 That the viability of the intestine cannot be determined
- 4 That an etiologic factor such as an invaginated Meckel's diverticulum or a pedunculated polyp cannot be removed at the time of the correction of the condition

The proponents of the reduction by barium enema state that the mortality and morbidity rates are low and that the dangers associated with the operative treatment in young infants are avoided. The recurrence rate after hydrostatic pressure reduction is somewhat higher, reaching 6% in some series as opposed to 2% for operative reduction. It has been pointed out by the proponents of the non-operative treatment that the postoperative mechanical obstruction from adhesions is less common in the conservative treatment and they recommend operative intervention for cases in the older age group, where an etiologic cause is more frequently demonstrable, and for recurrent cases, where one may more likely find a precipitating factor. Each method appears to have merit, and when properly applied for the individual case the mortality rate has been reduced from the initial 50% to less than 1%, an accomplishment which has only been superseded by the operative treatment of congenital hypertrophic pyloric stenosis.

COLON, RECTUM, AND ANUS

Embryology

The development of the rectum and anus is complicated by its close association with the developing urogenital system. In the 5-week embryo, the urogenital system and the hindgut open into a common cavity, the cloaca, which is closed off from the exterior by the cloacal

membrane. As growth progresses a urorectal septum of mesoderm descends toward the cloacal membrane, defining the urogenital system anteriorly and the hindgut posteriorly. The diminishing communication between the urogenital system and the hindgut is known as the cloacal sinus. When the urorectal septum reaches the cloacal membrane it forms the perineum and divides the cloacal membrane anteriorly to leave the urogenital membrane posteriorly. The urogenital membrane perforates at about the 7th to 8th week. The anal canal develops externally to form the proctodeum. This structure is surrounded by mesodermal elements which give rise to the external anal sphincter. The hindgut and the proctodeum meet at the anal membrane, which perforates at about the 9th week to form the anorectal canal.

Congenital Anomalies of Rectum and Anus

Arrest or abnormal development during the critical period from the 6th to 9th week gives rise to the various anomalies of the rectum and anus.

Anal Stenosis.—Perforation of the anal membrane occurs, but the anal canal remains narrowed.

Imperforate Anus.—This is of varying degree which may be classified into three main types:

- 1 **Membranous.** There is persistence of the anal membrane.
- 2 **Absence of anal canal.** There is failure of development of the canal, and the rectum ends as a blind pouch at a distance from the skin. This is the common form of malformation occurring in 80% of cases.
- 3 **Presence of anal canal.** The anal canal is normal, but the rectal pouch is a blind sac. Some distance separates the proctodeal cul-de-sac from the blind rectal pouch.

Associated Fistulas.—Persistence of the cloacal sinus gives rise to fistulas between the urogenital system or perineum and the hindgut which are present in most anomalies of the rectum and anus and must be searched for carefully. The rectoperineal fistula is common to both sexes. In the male the rectum may communicate with the trigone of the bladder, i.e., a rectovesical fistula, or with the prostatic

Fig 404—Congenital stenosis and types of imperforate anus. Treatment in I and II is a simple dilatation or a cruciate incision in the anal diaphragm. Treatment in III and IV requires considerable mobilization of the proximal bowel. (After Gross.)

Fig 405—Imperforate anus with associated fistula. (After Gross.)

Male

- A, Rectovesical fistula
- B, Rectourethral fistula
- C, Rectoperineal fistula

Female

- D, Rectovaginal fistula
- E, Rectofossa navicularis fistula
- F, Rectoperineal fistula

or membranous urethra, i.e., a rectourethral fistula. In the female the rectum may end in the posterior vaginal wall, commonly in the lower third, to give a rectovaginal fistula. Rectovesical and rectourethral fistulas are rare in the female but do occur.

Clinical Features.—*Anal stenosis* causes partial obstruction, with obstipation or the appearance of ribbonlike stools. *Imperforate anus* is usually associated with complete intestinal obstruction. However, a rectoperineal or rectovaginal fistula may be large enough to modify the clinical picture to that of partial obstruction. The passage of meconium rules out a complete obstruction. The presence of meconium in the urine indicates the presence of a rectourinary fistula.

Plain lateral films are then taken with the child inverted, or lying on his back with the thighs flexed on the abdomen, and a radiopaque marker placed at the anal dimple. The distance between the marker and the air shadow in the rectum can be measured. This procedure is most important in evaluating the malformation and determining the surgical approach to its correction.

At operation the perineum may be explored with a syringe and needle before the approach is decided. If meconium is aspirated, Lipiodol may be injected into the rectum to outline the blind sac. X-ray will then show the true degree of the defect. Malformation of the rectum and anus has a high incidence of associated anomalies, particularly of the upper urinary

Fig. 406—A, Imperforate anus in a male with a small midline perineal fistula. B, Imperforate anus in a female.

The perineum of the child must be examined carefully. The absence of the anus is easily noted. In the membranous imperforate anus, the anal membrane appears black and bulging due to the presence of meconium. A perineal or vaginal fistula will be evident by the passage of meconium at an abnormal site. Examination of the anal canal will reveal a stenosis or the persistence of the anal membrane at the end of a normal anal canal. X-ray examination of the abdomen confirms the diagnosis and is used to determine the degree of the defect between the rectum and anus. If the examination is delayed 12-24 hours, gas in the intestinal tract will have reached the

tract. Severe defects of the ureters or kidneys should be ruled out before operation by intravenous pyelography.

Treatment.—Anal stenosis is treated by repeated dilatation, which can be done by the parents at home. The membranous type of imperforate anus is relieved by a cruciate incision of the membrane. Dilatations are then started and repeated at regular intervals as in anal stenosis.

The imperforate anus with no anal canal may be approached by two methods which are determined by the distance between the rectum and the skin of the perineum.

1. *Perineal Approach*—This is used if the defect is less than 2 cm. Careful dissection of the perineum is carried out in the midline, deep to the anal dimple, until the blind rectal pouch is found, mobilized, and brought through the external anal sphincter and sutured to the skin without tension.

2. *Abdominoperineal Approach*—This is used if the rectum is high in the pelvis. In small infants a transverse colostomy may be performed as an interval procedure until the child has reached a weight of 10 kg. The

a fistula to the urinary tract must be treated immediately because of the hazard of an ascending urinary infection. A formal abdominoperineal repair is indicated, but a transverse colostomy may again be used as a temporizing measure. Low rectovaginal and rectoperineal fistulas are repaired by the perineal approach, lifting the fistula over the perineum and bringing the bowel down through the anal sphincter. Frequently these fistulas may be dilated to allow adequate gastrointestinal function. Repair may then be delayed past the neonatal period and performed as an elective procedure at an older age.

Congenital Megacolon (Hirschsprung's Disease)

Congenital megacolon, although rather well documented in the literature prior to the publication of Hirschsprung in 1888, is now known as Hirschsprung's disease, and while many theories have been advanced as to its etiology, it has only been in recent years that a definitive theory has been universally accepted as to the precipitating etiologic factor. There is a congenital absence of the ganglion cells in the myenteric plexus of Auerbach situated in the pelvic colon, which may extend cephalad up the colon for varying distances. In the affected area there is absence of peristaltic activity, and this region acts as a physiologic obstruction to the forward propulsion of gas, fluid, and feces. The normal proximal colon becomes dilated and hypertrophied, while the affected segment, although patent, remains of normal caliber. With this understanding of the causation of the condition, surgical therapy has kept pace and now offers definitive cure for these patients. With vigilance and cognizance of the condition, the diagnosis is being made more frequently in the neonatal period. With the realization that the underlying etiology is an absence of ganglion cells in the myenteric plexus of the rectum, the rectosigmoid, and sigmoid, attention has been withdrawn from the dilated and hypertrophied bowel which occurs proximally to this area, and emphasis has been placed on the site of physiologic obstruction that results from the absence of adequate peristalsis in this narrow segment of colon. Primary or congenital

Fig 407—Imperforate anus. Plain film, with patient inverted in the buttocks up position, showing gas in the rectal pouch at a distance from a marker placed in the perineum.

definitive procedure mobilizes the sigmoid and rectum down to the levator ani muscles. A perineal dissection is then made and the bowel pulled through the levator ani muscles and external anal sphincter and anchored to the skin.

The high incidence of fistulas associated with imperforate anus requires most careful dissection of the blind pouch of the rectum to identify possible fistulas. The presence of

megacolon must be differentiated from secondary megacolon which may be present proximal to an anal stenosis or strictures or present in those children who withhold stool for one reason or another. The onset of symptoms may appear shortly after birth. It has been pointed out that in children who have undergone laparotomy for intestinal obstruction in the newborn period, where no mechanical block is found, congenital megacolon should be strongly suspected and colostomy performed. Histologic section of the colon reveals the absence of ganglion cells, which

Palpation or visualization of the fecal masses in the greatly enlarged colon is often possible, and peristaltic waves may be seen through the thin, tense anterior abdominal wall. Rectal examination, while inconclusive in the newborn infant, is frequently of diagnostic significance in the older child, where the rectum appears to be normal in diameter, and in those children with sigmoid impaction a large bolus of stool may be felt with the examining finger. While constipation is the rule, diarrhea may occur when liquid feces pass around the impacted mass of stool. Many of these children

Fig 408—Congenital megacolon. Marked distention of the abdomen due to accumulated feces. A, In an infant. B, In a young child.

appears to be an all-or-none phenomenon. In very small infants with the onset of symptoms shortly after birth, it would appear that there is a more severe degree of aganglionosis and that this defect may be carried well proximal to the sigmoid colon. There is a sex ratio, 9 males to 1 female. Persistent constipation with enlargement of the abdomen, elevation of the leaves of the diaphragm, anorexia, and evidence of malnutrition may be present

with Hirschsprung's disease. Children with megaloblasts and megaloureters, presumably from the same neurologic deficit, and it is important to investigate the urinary tract. X-ray examination of the abdomen is often helpful in confirming a diagnosis, and a markedly dilated colon containing large amounts of gas and feces should arouse suspicion. Careful examination of the large bowel with limited amounts of barium will reveal that no me-

life to adolescence Unlike multiple polyposis or the isolated polyp in the adult, there is little tendency to malignant degeneration The patient may present with (1) bleeding per rectum, (2) prolapse of a polyp through the anus, or (3) intussusception Rectal and sigmoidoscopic examination will demonstrate their presence in the lower bowel. Once the diagnosis is suspected, a barium enema must be given to rule out polyps at a higher level

Fig 410—Rectal polyp outlined by barium after evacuation

Postevacuation films after a barium enema are essential to demonstrate the polyps Other causes of bleeding per rectum in the child must be excluded (1) fissure-in-ano, (2) Meckel's diverticulum, (3) intussusception, (4) intestinal duplication, and (5) hemorrhagic diseases

The treatment of the isolated polyps in children is removal by snare and cauterization of those polyps that can be reached by proctoscope Polyps high in the sigmoid or proximal intestine must be removed by abdominal exploration with ileotomy or colotomy over the site of the individual polyp

BILIARY SYSTEM, LIVER, AND PORTAL HYPERTENSION

Obstructive Jaundice in Infancy

The persistence of jaundice in the infant past the newborn period poses a difficult problem in differential diagnosis. Conditions of surgical importance are those causing obstructive as distinguished from nonobstructive jaundice, by the presence of acholic stools and dark bile-stained urine. (See Chapter 19.) Obstruction to the flow of bile in the infant is caused by (1) inspissated bile pigments, (2) congenital atresia of the bile ducts, and (3) neonatal hepatitis Mucous plugs in the common duct and extraluminal compression of the biliary system may be additional but rare causes. Unless the obstruction is relieved there may be irreversible hepatic changes and biliary cirrhosis

Inspissation of bile pigments in the bile ducts and canaliculi occurs with excessive hemolysis and is seen in erythroblastosis fetalis (Rh sensitivity) and icterus precox (ABO sensitivity) Hematologic tests for erythrocyte fragility, infant and maternal blood group incompatibility, and antibody determinations will isolate cases of obstructive jaundice due to increased hemolysis These conditions should be anticipated by antenatal blood studies of the mother and exchange transfusion of the infant after birth Most cases of bile pigment obstruction will respond to expectant therapy with the use of chologogues Severe blockage of the bile ducts may require laparotomy and washing out of the bile plugs

Unfortunately, in obstructive jaundice due to congenital atresia of the bile ducts or neonatal hepatitis, the clinical picture is identical and laparotomy examinations will not give a clear differential diagnosis A steadily rising bilirubin is suggestive of biliary atresia, but the values may fluctuate widely in either condition Other tests of liver function are even more confusing Twenty per cent of the anomalies found in congenital atresia of the bile ducts can be treated surgically (see congenital atresia of the bile ducts, Chapter 20) It is of utmost importance that a definite diagnosis be established before the progressive changes of biliary cirrhosis occur Experience has shown

that in most cases of obstructive jaundice, in infants will succumb to the effects of biliary cirrhosis, even if the obstruction is relieved early. For this reason a diagnostic laparotomy is required at or prior to 1 month of age. The procedure is not extensive. A small incision is made over the liver, sufficient to allow inspection of the subhepatic area. An absence of the gall bladder indicates that there is a probable extrahepatic biliary atresia. If the gall bladder is present it is catheterized and a cholangiogram obtained. At the same time a liver biopsy is taken. The incision is then closed, and if the gall bladder has been catheterized, the tube is left in place for drainage and used for repeated cholangiographic studies if necessary. Correlation of the cholangiogram and the pathologic findings of the liver biopsy will furnish a correct diagnosis. Liver biopsy will establish the diagnosis of intrahepatic biliary atresia, for which there is no treatment, extrahepatic biliary obstruction manifested by the presence of some degree of biliary cirrhosis, or the hepatocellular changes of neonatal hepatitis. Cholangiogram will demonstrate the site of the extrahepatic biliary obstruction. An early definitive approach may then be planned for a proved case of extrahepatic biliary atresia, and the child with neonatal hepatitis has not been subjected to a prolonged surgical exploration of the biliary system. This technique has improved the prognosis in those cases of biliary atresia that are amenable to surgical correction.

Portal Hypertension in Childhood

Our experience with 21 patients operated upon for portal hypertension (1919-1956) is given in brief below to indicate the peculiarities and difficulties encountered in the handling of this entity in a children's hospital. (See also Chapter 19.)

Etiology.—Unlike the portal hypertension which manifests itself in adult life, our cases have been confined to those classified as subhepatic or extrahepatic portal obstruction, and rarely have we seen hepatic cirrhosis as the precipitating factor. The causes of extrahepatic portal block have been arranged in an interest-

ing classification which includes (1) trauma, (2) postoperative mesenteric vein thrombosis, (3) systemic infections, (4) neonatal omphalitis, and (5) congenital absence of intrahepatic portal venous radicals.

Neonatal omphalitis is the most common cause of portal hypertension in childhood. The infection spreads up the lumen of the umbilical vein, which runs in the free edge of the falciform ligament, and an accompanying septic thrombosis passes from the umbilical vein to the portal vein via intercommunications. Recanalization creates a condition which is known as *cavernomatous degeneration* or *transformation of the portal vein*, the result of which is an extrahepatic portal block and an inflammatory reaction at the porta hepatis. Blockage of the flow of blood in the portal vein gives rise to portal hypertension and is manifested by hemorrhage from esophageal varices and splenomegaly. Massive hematemesis in a previously normal child or the designation of increased portal pressure. In some cases (hypersplenism) may suggest radiographic and esophagoscopy studies, with the visualization of esophageal varices. In a child the commonest cause of massive hematemesis is bleeding from such varices, as the other conditions encountered in adults are uncommon.

Treatment.—When severe hypersplenism exists the treatment is splenectomy. In children over 5 years of age, splenotomal anastomosis should be attempted unless the splenic vein is hopelessly inadequate in caliber. In extrahepatic portal obstruction, portacaval anastomosis is often impossible because of cavernomatous transformation of the portal vein.

We have performed a transesophageal ligation of varices in seven patients with extrahepatic portal block for recurrent hemorrhage. One patient had a previous portacaval anastomosis, two a splenorenal anastomosis, and all a splenectomy. Only two of these patients have rehemorrhaged. Results of the shunt procedures in childhood have been disappointing. Perhaps in extrahepatic obstructions, splenectomy alone, accompanied by transesophageal ligation of varices, will become an accepted procedure. Clatworthy has attempted

end-to-end anastomosis of the superior mesenteric vein to the cut proximal inferior vena cava in cases where other previous anastomoses have failed

We have reduced portal pressures from over 600 mm of saline to under 300 mm by means of shunting procedures on several occasions in children and have had recurrent bleeding in all cases. There is no evidence that these small caliber venovenous anastomoses remain patent in children.

PERITONEUM, OMENTUM, AND MESENTERIES

Primary Peritonitis

Primary peritonitis is a condition which is found most commonly in infancy and early childhood. The peritonitis does not arise from an inflammatory focus within the peritoneal cavity but is probably carried there during bacteremia. It was once thought that the most common organism was the pneumococcus and that this condition occurred almost exclusively in females, the infection being carried to the peritoneum by way of the fallopian tubes. It is now known that the most common organism is the hemolytic streptococcus and that the sex incidence is about equal. More than two thirds of the patients are under 5 years of age. The illness usually begins with an upper respiratory tract infection, which is rapidly followed by severe abdominal pain and by vomiting which may progress to dehydration. Diarrhea is not uncommon in the early stages, but as the peritonitis progresses constipation or obstipation is the rule. The picture is one of extreme toxicity with high fever and rapid pulse. The abdomen is distended, doughy to palpation, and diffusely tender without localized tenderness. Rectal examination reveals diffuse pelvic tenderness. The white blood count is elevated and ranges from 30,000-60,000, 80-90% being polymorphonuclear leukocytes. The presence of pneumonia in infants and young children must be excluded by x-ray, and this may be exceedingly difficult because pneumonia and primary peritonitis may occur simultaneously in the very young infant. This condition must be differentiated from a generalized secondary peritonitis, the commonest source of which is a ruptured ap-

pendix. Acute appendicitis is rare under the age of 2 years and uncommon under the age of 3 years. The progression of the abdominal symptoms of an acute appendicitis, with periumbilical pain and localization to the right lower quadrant before the onset of generalized peritonitis, is the usual picture, while in primary peritonitis the tenderness is diffuse from the beginning. The association with an upper respiratory tract infection, the onset with chill and high fever, the severe toxicity, and the markedly elevated white count all help to make an adequate diagnosis which is only possible in two thirds of the cases, necessitating confirmation by limited laparotomy. The contraindications to limited laparotomy are (1) nephrosis, where the association of primary peritonitis is common and antibiotic therapy is proving satisfactory, and (2) marked toxicity and sepsis from some generalized condition in which the peritonitis is only a part. On opening the peritoneal cavity the odor of the contents should be carefully noted, and if not feculent, suspicion should be aroused. A smear of the peritoneal exudate should be examined immediately. If the streptococcus or pneumococcus is demonstrated, the diagnosis is confirmed. As much exudate as possible should be aspirated through the small incision and a Penrose drain inserted into the pelvis. The postoperative care after this diagnostic laparotomy is of utmost importance. Penicillin is the antibiotic of choice and should be given in large doses until all the acute symptoms have subsided for several days. Adequate sedation must be used. The infant does best in an atmosphere of high oxygen content. Continuous Wangenstein suction with a Levin tube in the stomach should be used until the bowel sounds are well heard and the infant has passed feces and flatus. Nutrition should be maintained by the intravenous route and blood or packed red blood cells administered to combat the anemia which is so often present in these infants with overwhelming peritonitis. Concentrated human serum albumin can be employed for the correction of hypoproteinemia. The drain into the peritoneal cavity should be mobilized in 48 hours and then gradually shortened day by day until completely removed.

It is extremely important to recognize this condition in the young infant and child. Failure to suspect it or extensive laparotomy to find a source of primary infection within the peritoneal cavity is accompanied by increased morbidity and mortality. The institution of 1 million units crystalline penicillin and 1 Gm streptomycin into the peritoneal cavity is a procedure which may be useful. With the advent of antibiotic therapy and its institution from the very beginning of this condition, together with a limited laparotomy and adequate postoperative care, the mortality rate from primary peritonitis has been considerably diminished.

mesentery of the small bowel or between the layers of the mesocolon.

Etiology.—It is thought that these cysts develop from ectopic rests of lymphatic tissue, which continue to secrete and enlarge because of lack of communication with the normal lymphatic channels. They are most commonly found between the leaves of the mesentery of the jejunum or the ileum but may occur between the layers of the mesocolon throughout its entire length. They are soft and the contents may vary greatly in volume. Some, occurring between the leaves of the mesentery of the small intestine, contain chyle and are known as *chylous cysts*. Other mesenteric cysts contain a serous fluid similar to that of plasma in concentration and composition.

Diagnosis.—These children usually present with a painless, slowly increasing growth of the abdomen. The cysts may cause intermittent crampy abdominal pain and occasional vomiting, or rarely give rise to acute intestinal obstruction when the cystic mass is saddle-shaped, resting on the adjacent bowel and obstructing its lumen. In most cases a soft fluctuant swelling can be palpated within the abdomen which appears to be rather freely mobile. X-ray examination may reveal a space-occupying lesion displacing intestinal loops, and pneumoperitoneum may afford better visualization.

Treatment.—In many instances it is possible to dissect the cyst from between the layers of the mesentery without damage to the arterial or venous supply to the intestine. Sometimes, because of the size of the cyst and its proximity to the intestine, it may be necessary to resect the adjacent intestine with the cyst in order to preserve the blood supply to the bowel.

Omental Cysts

Embryology.—These thin-walled unilocular or multilocular cystic masses which appear in the omentum are thought to arise from developmental anomalies of the lymphatics within this structure. They are lined by a single layer of endothelial cells and filled with a clear serous fluid. Enlargement occurs slowly except when sudden hemorrhage into the loculated structures of the cyst causes rapid change in size.

Signs and Symptoms.—These children usually present with a history of a gradual enlargement of the abdomen, and on physical examination a soft palpable mass may be felt anywhere in the abdominal cavity, depending on the site of the cyst at the time. A space-occupying lesion can be visualized by x-ray, and if it lies in the anterior portion of the abdominal cavity, an omental cyst may be suspected. A further diagnostic aid is the use of pneumoperitoneum, and x-ray studies with this double contrast medium will outline the cystic mass.

Treatment.—The treatment of choice is simple excision. The smaller omental cysts can be readily dissected from between the leaves of the omentum. The larger varieties may require resection of most of the omentum to ensure removal of the entire cyst.

Mesenteric Cysts

Definition.—These are smooth, thin-walled masses which lie between the leaves of the

ABDOMINAL WALL

Congenital Absence of the Abdominal Musculature

This is a condition which has been reported with increasing frequency in recent years. The three main groups of associated anomalies are found in the genitourinary tract, the gastrointestinal tract, and in the extremities. The genitourinary anomalies that occur most fre-

quently with the absence of abdominal musculature comprise hydroureter, hydronephrosis, and an enlarged bladder. The etiology of this condition is obscure. There is a strong preponderance in the male sex, and because of this, the theory of a primary genitourinary tract obstruction as an etiologic factor is proposed by Spumme since such obstructions are more commonly found in the male infant. Another, almost constant finding is failure of the

is extremely variable and depends on early diagnosis and correction of the associated anomalies.

Neoplasms of the Abdominal Wall

Neoplastic masses may appear in any portion of the anterior abdominal wall, and the majority are present at birth. The most common mass is a *hemangioma*, which may be capillary or cavernomatous in type and is benign. The treatment is surgical excision and repair of the defect in the anterior abdominal wall. *Lipomas* of the anterior abdominal wall, frequently associated with lipomatous masses elsewhere, are common. They are characteristic in appearance and present a typical roentgenologic picture. The treatment is simple excision.

The Desmoid Tumor.—The desmoid tumor of the rectus sheath is characteristically found anterior to the sheath and occurs more frequently below the level of the umbilicus. It presents a firm, asymptomatic, ovoid mass which is not well circumscribed and is attached deeply to the rectus sheath. This tumor tends to recur locally and, for this reason, primary excision should be complete.

The Umbilicus

Omphalocele

Definition.—During the 5th to 10th week of intrauterine life, a discrepancy between the size of the developing intra-abdominal structures and the size of the celomic cavity which contains them results in the physiologic herniation of the midgut, sometimes accompanied by a portion of the liver, into the base of the umbilical cord. If the structures of the midgut remain too large, or the celomic cavity is too small to contain them, this physiologic herniation may persist as an *omphalocele*. Normally, the structures of the midgut are returned to the peritoneal cavity in a definitive manner at about the 10th week of intrauterine life. The hernia in the base of the umbilical cord is characteristic: (1) the two umbilical arteries and the umbilical vein may be seen coursing over its surface, and (2) the pro-

Fig. 411.—Congenital absence of abdominal musculature

descent of the testes into the scrotal sac. Whatever the cause, the disturbance in embryogenesis must occur before the 10th week of fetal life. The constant physical findings are those associated with absence of the abdominal musculature and flaring of the lower rib cage. The abdominal wall is soft and the abdominal organs can be readily palpated. The prognosis

truded abdominal contents may be visualized through the thin, translucent avascular covering of the pouch, which consists only of the peritoneum and amniotic membrane. The size of the sac may be quite variable but on the average measures 10 cm in diameter. The size of this sac is not related to the size of the opening at the umbilicus through which the intestinal contents protrude. Because of the perishable nature of the covering membranes and their avascularity, this condition becomes one of the most urgent observed in the delivery room. Indeed, it has been said that these babies should be transferred from the arms of the obstetrician to the arms of the surgeon. During

Fig 412—Omphalocele. A large herniation into the umbilical cord through a comparatively small defect at the umbilicus.

The operative correction can be approached in two ways: (1) If the pouch and its contents are small, the pouch can be emptied by the replacement of the abdominal viscera into the peritoneal cavity, excision of the skin at the base of the pouch carried out, and repair of the anterior abdominal wall accomplished in a one-stage procedure. (2) However, if the omphalocele is large this may present a formidable problem. It may be necessary to accomplish the repair in a two-stage procedure: (a) Excision of the pouch is made down to the point where fresh skin edges can be obtained with closure of these freshened skin edges and subcutaneous tissue over the protruding mass of abdominal viscera. In these large omphaloceles there is little risk in burying the covering of peritoneum and amniotic membrane under the skin if it has been carefully cleansed with a bland detergent. Post-operative support by the use of a binder or an elastic bandage can be instituted, and this gentle pressure is maintained until the peritoneal cavity is of sufficient capacity to contain the abdominal viscera. After 10-12 weeks it is usually possible to pick up the covering skin and see that the abdominal contents can remain intraperitoneally. (b) At this time a second stage is undertaken in which the defect in the anterior abdominal wall is repaired and the redundant skin excised and closed.

Cyst of the Umbilical Cord

Throughout any length of the umbilical cord large collections of Wharton's jelly may occur and distend it in a cystic manner. The complications of this event are twofold: (1) a large cyst may interfere with delivery of the baby, and (2) a cyst may appear at the base, complicating the tying of the cord at birth. If there is little space between the proximal portion of the cord and the anterior abdominal wall, the vessels of the cord must be tied distal to the cyst, but because of the nature of the cyst covering, its avascularity, and its tendency to early drying, surgical removal should be attempted as soon as possible. Treatment is surgical excision of the cyst and ligation of the two umbilical arteries and the vein on the abdominal side of the structure.

the first few hours of life the sac remains moist and will permit a certain amount of gentle handling, but later, with drying and because of the avascularity, evisceration and infection will occur. It is important to realize that the persistence of this midgut hernia is almost always associated with some degree of failure of rotation of the intestine. Definitive corrective surgery is carried out most easily before the contents of the pouch have become distended with gas and fluid. There is no place for watchful waiting in the treatment of this condition.

quently with the absence of abdominal musculature comprise hydronephrosis, hydronephrosis, and an enlarged bladder. The etiology of this condition is obscure. There is a strong preponderance in the male sex, and because of this, the theory of a primary genitourinary tract obstruction as an etiologic factor is proposed by Spumme since such obstructions are more commonly found in the male infant. Another, almost constant finding is failure of the

is extremely variable and depends on early diagnosis and correction of the associated anomalies

Neoplasms of the Abdominal Wall

Neoplastic masses may appear in any portion of the anterior abdominal wall, and the majority are present at birth. The most common mass is a *hemangioma*, which may be capillary or cavernomatous in type and is benign. The treatment is surgical excision and repair of the defect in the anterior abdominal wall. *Lipomas* of the anterior abdominal wall, frequently associated with lipomatous masses elsewhere, are common. They are characteristic in appearance and present a typical roentgenologic picture. The treatment is simple excision.

The Desmoid Tumor.—The desmoid tumor of the rectus sheath is characteristically found anterior to the sheath and occurs more frequently below the level of the umbilicus. It presents a firm, asymptomatic, ovoid mass which is not well circumscribed and is attached deeply to the rectus sheath. This tumor tends to recur locally and, for this reason, primary excision should be complete.

The Umbilicus

Omphalocele

Definition.—During the 5th to 10th week of intrauterine life, a discrepancy between the size of the developing intra-abdominal structures and the size of the celomic cavity which contains them results in the physiologic herniation of the midgut, sometimes accompanied by a portion of the liver, into the base of the umbilical cord. If the structures of the midgut remain too large, or the celomic cavity is too small to contain them, this physiologic herniation may persist as an *omphalocele*. Normally, the structures of the midgut are returned to the peritoneal cavity in a definitive manner at about the 10th week of intrauterine life. The hernia in the base of the umbilical cord is characteristic. (1) the two umbilical arteries and the umbilical vein may be seen coursing over its surface, and (2) the pro-

Fig. 411—Congenital absence of abdominal musculature

descent of the testes into the scrotal sac. Whatever the cause, the disturbance in embryogenesis must occur before the 10th week of fetal life. The constant physical findings are those associated with absence of the abdominal musculature and flaring of the lower rib cage. The abdominal wall is soft and the abdominal organs can be readily palpated. The prognosis

organism is most sensitive. Warm, moist saline compresses should be applied to the local area, and when abscess formation occurs, an attempt should be made to drain these localizations of pus. With the advent of peritonitis the prognosis is extremely grave and the mortality rate in this condition can only be lowered by instituting the treatment that has been advocated for the therapy of a primary peritonitis.

Urachal Cyst and Sinus

In early embryonic life, the urinary bladder extends from the umbilicus down to the bladder neck. As caudal migration of the urinary vesicle occurs, a remnant of its umbilical attachment may persist which may be patent throughout, communicate both with the umbilicus and the dome of the bladder, and manifest itself by the periodic excretion of variable amounts of urine at the umbilicus. The urachal remnant may be obliterated at the umbilicus and at its attachment to the bladder to form a urachal cyst. This presents as a midline swelling in the lower abdomen. Diagnosis of the persistent urachus is accomplished by means of a cystogram, while the anterior extraperitoneal position of the midline mass of the urachal cyst is diagnostic. The treatment of both these conditions is surgical excision at the earliest moment, which is readily performed before infection has supervened.

HERNIA

(See also Chapter 29)

Umbilical Hernia

This is a common condition in infancy and childhood. It occurs at a point where there are muscular and fascial defects at the umbilicus. Unlike the omphalocele, it is never a surgical emergency. The peritoneum is closed and forms a sac which in this case is covered by skin and subcutaneous tissue. The hernial ring is usually firm, fibrous, and circular in shape and is formed by the fusion of the anterior and posterior rectus sheaths. This condition may be confined to the region of the umbilicus itself or may also appear above and below the umbilicus in the form of a supraumbilical or infraumbilical herniation. These weaknesses

can be detected in the early months of life and are readily observed in infants who have prolonged periods of crying or straining. They become more prominent when the patient assumes an upright position and vary in size and content. Their diameter ranges from 1-4 cm., and the contents may comprise omentum or omentum with a single loop of small intestine. The symptoms are usually mild. Incarceration is a rare complication and strangulation practically never occurs.

Treatment.—

CONSERVATIVE APPROACH.—It is important to realize that the vast majority of small umbilical hernias in infants will obliterate themselves as the child grows and, for this reason, do not require treatment. In the larger umbilical hernias, however, closure may be facilitated by the application of an adhesive

Fig 413.—Umbilical hernia

strapping over the region of the umbilicus under sufficient tension to give a vertical crease in the region of the umbilicus. If no improvement has occurred after 4-6 months of strapping it is futile to continue this therapy. Strapping probably plays no part in the cure of hernia in patients over the age of 6 months.

SURGICAL APPROACH.—The indications for umbilical herniorrhaphy depend on the age of the patient and the size of the neck of the sac. The umbilical hernial ring, 1 cm. or less in diameter, will usually close spontaneously. If the hernia is present at 2 years of age it

Persistent Granulation Tissue at the Umbilicus

Within the first few weeks of life and after the cord has separated, a small mass of granulation-like tissue may appear in the depths of the umbilicus. This mass may discharge a serosanguineous fluid and cause maceration of the skin of the newly healed umbilicus. This is usually a temporary condition which responds to cauterization with silver nitrate, but sometimes this conservative therapy is unsuccessful and surgical excision is necessary. In some of our cases this tissue sent for histologic section has revealed the presence of an intestinal-like mucosa which accounts for its continual secretion and resistance to conservative treatment.

Omphalitis

Omphalitis, which by definition means *inflammation of the navel*, is an all-inclusive term. Inflammatory conditions may involve one or more of the several structures, and these inflammations vary in their severity and in the specific type of complication which may result. The infection may be localized and remain so, or it may spread in the lymphatic drainage of the periumbilical region. The process may begin at the umbilicus and ascend the lumen of the umbilical vein or it may propagate in the lumen of the unobliterated umbilical arteries. The organisms most commonly found are the staphylococcus and the hemolytic streptococcus, but mixed infections are not uncommon, and that caused by an anaerobic streptococcus may be particularly difficult to treat.

Localized Omphalitis.—Localized superficial infections in the region of the umbilicus rarely give rise to serious complications and respond well to local treatment.

Migrating Infections of the Umbilicus.—Infections about the umbilicus spread in several definite ways. If the infection is complicated by lymphangitis it may give rise to inguinal adenitis or, spreading upward in the fascial planes, it may develop into a localized abscess of the abdominal wall. If the organism is an anaerobic streptococcus, an extensive panniculitis may supervene which may give rise to desquamation and sloughing of the

skin over the anterior abdominal wall above the umbilicus. This appears first in the regions where the bony structures of the sternum and ribs underlie the spreading infection. The breakdown of tissue may be rapid, but the initial inflammatory reaction about the umbilicus may have subsided by the time the abdominal musculature is laid bare. The treatment consists of warm, moist saline compresses which are changed frequently to accomplish an effective débridement of the dead and dying tissue. Cleansing with hydrogen peroxide facilitates this, and the use of zinc peroxide which releases nascent oxygen may prove beneficial. Once the infection has been brought under control, re-epithelization is usually rapid and proceeds centrally into the defect. Large skin defects require a thin Thiersch graft.

Infections Spreading in the Lumen of Umbilical Vessels.—This type of spreading omphalitis carries the highest morbidity and mortality along with serious and far-reaching consequences. While the lumen of these vessels usually obliterates shortly after birth, they may remain patent for several weeks. As a result of this, umbilical artery or vein infection may give rise to a bacteremia with all its consequences. If the infection becomes localized along the path of the umbilical artery or vein, it may give rise to an extraperitoneal abscess and this, in turn,

ward course in the lowermost edge of the falciform ligament and its communication with the portal vein and the inferior vena cava via the ductus venosus, inflammation may result in portal vein thrombosis. Such a thrombus organizes and becomes partially recanalized, giving rise to a condition which is known as *cavernomatous degeneration of the portal vein*, with an extrahepatic portal vein obstruction and portal hypertension as a possible complication.

Because of the extreme importance of omphalitis in the newborn infant, aseptic precautions should be carried out in the handling of the umbilical cord. If infection occurs, identification of the organism should be obtained, and the infant should be treated with massive doses of penicillin and the appropriate broad-spectrum antibiotic to which the

the cord have all enlarged to accommodate the hernia, and this is definitely discernible. The child will not tolerate invagination of the scrotum by the examining finger as will the adult, as the scrotum has not developed sufficiently to allow this procedure. The reduction of a hernial mass confirms the diagnosis.

Differential Diagnosis.—An inguinal hernia can be differentiated from (1) hydrocele, (2) acute inguinal adenitis, and (3) cryptorchidism with the testis in the canal. The hydrocele is firm, will not reduce, and transilluminates. Also it is possible to define the upper limits of the cyst outside the external ring. However, the presence of a hydrocele does not rule out an associated hernia. An *acute inguinal adenitis* may simulate an incarcerated hernia, as these nodes overlie the small inguinal canal of the child. The progressive symptoms of incarceration are not present, and there is usually evidence of inflammation. The child must be watched very closely to determine the true diagnosis. The *partially descended testicle* can be readily recognized by its absence from the scrotum.

Treatment.—A patent processus vaginalis or potential hernial sac may disappear in the first few months of life. However, once a hernial mass has become apparent, it is very rare for it to disappear. Small hernias in infants under 1 year may regress. If the hernia is large or the child is aged over 1 year, the processus will not obliterate spontaneously. Once the diagnosis has been made, corrective surgery should be done. With adequate facilities for pediatric anesthesia and surgery, infants tolerate the procedure well and there is little risk. It is done as an elective operation, but the parents must be fully aware of the possibility of incarceration in the infant, which then presents an emergency situation. Intestinal obstruction and gangrene of the testis may be in infants. The operation may be delayed until after the child has passed the neonatal period and is thriving. In our hospital this is set arbitrarily at 3 months, or when the infant weighs 5 kg. The use of a truss as a specific treatment has been discarded.

Operation.—The operation for hernia in children is directed at removing the patent

processus vaginalis. Unless the hernia is unusually large the walls of the inguinal canal are normal and intact. A transverse incision is made in the skin crease over the canal. The external oblique is opened to the level of the subcutaneous inguinal ring to expose the cord. The hernial sac is then defined and dissected to the deep inguinal ring, where it is ligated and excised. The cord is returned to the canal. It is rarely necessary to decrease the internal ring by suturing the conjoined tendon to Poupart's ligament (Bassini repair). The external oblique, Scarpa's fascia, and the skin are closed in layers.

With this type of inguinal herniorrhaphy, limited to simple excision of the sac, the recurrence rate is less than 2%, which is more acceptable than a 10% incidence of testicular atrophy found in infants who have had a more extensive type of hernial repair. Recurrence is associated almost entirely with the emergency treatment of incarcerated hernias.

Postoperative Care.—Feedings are started in 4 hours, and the patient discharged on the 2nd postoperative day.

Diaphragmatic Hernia

Defects in the diaphragm, which give rise to hernias in infants and children, are almost entirely congenital in origin. However, traumatic hernias must be considered in compression injuries of the chest and abdomen.

Embryology.—The diaphragm develops as a muscular partition between the pleural and abdominal cavities. The central portion is formed by the ventral *septum transversum* and the dorsal mesentery. At this stage the pleural cavity on each side still communicates with the abdominal cavity through the pleuroperitoneal canals. This defect is then closed by a double serosal layer contributed by the peritoneum and pleura. Muscular elements of central and dorsal portions and, to a lesser degree, the body wall develop in this layer to form the muscular diaphragm with its central tendon. During its development the diaphragm incorporates or surrounds the contents of the dorsal mesentery—the foregut, the aorta, and the inferior vena cava. (See also p. 772 and Fig 374.)

should be repaired. Those with a fascial defect larger than 2 cm., and particularly those that contain bowel, are increasing in size, or give rise to occasional symptoms, should be treated by surgical correction.

Operation—There is no place in the surgical repair of the umbilical hernia in infancy for a procedure that does not preserve the normal umbilical depression. A periumbilical crescentic incision is made through the skin and subcutaneous tissue, and through this incision the hernial sac is isolated. The sac is then inverted into the peritoneal cavity and the medial aspects of both rectus muscles are approximated in the midline by a vertical row of interrupted sutures. Because of the vascularity in the periumbilical region and its tendency to produce a serous collection, the dome of the protruding skin should be sutured to the anterior rectus sheath. An occlusive dressing with lateral compression is applied. The older method of subcutaneous ligation of the hernial sac through three small incisions is not recommended. The occurrence of umbilical hernia is more common in female than in male infants, and because of the increase in the size of the abdomen with pregnancy, it is important that these larger hernias be treated by a surgical approach in the young female.

Inguinal Hernia

Inguinal hernias seen in children are congenital remnants of the processus vaginalis which may remain patent to give an indirect, complete, or scrotal hernia. Persistence of a portion of the processus may give rise to an incomplete hernia, a hydrocele of the testis or tunica vaginalis, an encysted hydrocele of the cord in the male, or a cyst of the canal of Nuck in the female. As the right testicle descends after the left, the processus on the right closes at a later stage, which probably explains the higher incidence of right inguinal hernia. The experience of Gross is that 60% occur on the right, 15% are bilateral, and 25% occur on the left side. The presence of a left inguinal hernia demands a careful examination of the right side, as a bilateral hernia may be present. Ninety per cent of the hernias occur in the male. (See Fig 360)

Clinical Features and Diagnosis.—1... hernia may be present at birth, but more usually it becomes apparent after a few months and may present as a bulge at the external ring or descend into the scrotum. The contents are small bowel, cecum, or sigmoid, as the omentum has not developed sufficiently to reach into the hernial sac. In females, the contents are very frequently an ovary and fallopian tube because of the shallow pelvis and the association of the round ligament of the uterus with the inguinal canal. The parents' observation of a swelling in the groin may be the only specific indication of a hernia. In older children with large hernias there may

Fig 414—Left inguinal hernia

be local discomfort. The chief hazard is incarceration, which is most common in the first year of life and may be the first evidence of a hernia. The swelling is tense, and the child is in obvious pain. If it has persisted for some time, vomiting occurs, and the condition progresses to strangulation of the bowel and intestinal obstruction.

Inspection is the first examination for hernia. Increasing the intra-abdominal pressure by allowing the infant to cry or by having the older child stand will frequently produce the telltale bulge. Gentle palpation of the spermatic cord by rolling it under the finger tip will demonstrate a definite thickening on the suspected side. Even if the sac is empty the structures of

the cord have all enlarged to accommodate the hernia, and this is definitely discernible. The child will not tolerate invagination of the scrotum by the examining finger as will the adult, as the scrotum has not developed sufficiently to allow this procedure. The reduction of a hernial mass confirms the diagnosis.

Differential Diagnosis.—An inguinal hernia can be differentiated from (1) hydrocele, (2) acute inguinal adenitis, and (3) cryptorchidism with the testis in the canal. The hydrocele is firm, will not reduce, and transilluminates. Also it is possible to define the upper limits of the cyst outside the external ring. However, the presence of a hydrocele does not rule out an associated hernia. An *acute inguinal adenitis* may simulate an incarcerated hernia, as these nodes overlie the small inguinal canal of the child. The progressive symptoms of incarceration are not present, and there is usually evidence of inflammation. The child must be watched very closely to determine the true diagnosis. The *partially descended testicle* can be readily recognized by its absence from the scrotum.

Treatment.—A patent processus vaginalis or potential hernial sac may disappear in the first few months of life. However, once a hernial mass has become apparent, it is very rare for it to disappear. Small hernias in infants under 1 year may regress. If the hernia is large or the child is aged over 1 year, the processus will not obliterate spontaneously. Once the diagnosis has been made corrective surgery should be done. With adequate facilities for pediatric anesthesia and surgery, infants tolerate the procedure well and there is little risk. It is done as an elective operation, but the parents must be fully aware of the possibility of incarceration in the infant, which then presents an emergency situation. Intestinal obstruction and gangrene of the testis may be complications of persistent incarceration in infants. The operation may be delayed until after the child has passed the neonatal period and is thriving. In our hospital this is set arbitrarily at 3 months, or when the infant weighs 5 kg. The use of a truss as a specific treatment has been discarded.

Operation.—The operation for hernia in children is directed at removing the patent

processus vaginalis. Unless the hernia is unusually large the walls of the inguinal canal are normal and intact. A transverse incision is made in the skin crease over the canal. The external oblique is opened to the level of the subcutaneous inguinal ring to expose the cord. The hernial sac is then defined and dissected to the deep inguinal ring, where it is ligated and excised. The cord is returned to the canal. It is rarely necessary to decrease the internal ring by suturing the conjoined tendon to Poupart's ligament (Bassini repair). The external oblique, Scarpa's fascia, and the skin are closed in layers.

With this type of inguinal herniorrhaphy, limited to simple excision of the sac, the recurrence rate is less than 2%, which is more acceptable than a 10% incidence of testicular atrophy found in infants who have had a more extensive type of hernial repair. Recurrence is associated almost entirely with the emergency treatment of incarcerated hernias.

Postoperative Care.—Feedings are started in 4 hours, and the patient discharged on the 2nd postoperative day.

Diaphragmatic Hernia

Defects in the diaphragm, which give rise to hernias in infants and children, are almost entirely congenital in origin. However, traumatic hernias must be considered in compression injuries of the chest and abdomen.

Embryology.—The diaphragm develops as a muscular partition between the pleural and abdominal cavities. The central portion is formed by the ventral *septum transversum* and the dorsal mesentery. At this stage the pleural cavity on each side still communicates with the abdominal cavity through the pleuroperitoneal canals. This defect is then closed by a double serosal layer contributed by the peritoneum and pleura. Muscular elements of central and dorsal portions and, to a lesser degree, the body wall develop in this layer to form the muscular diaphragm with its central tendon. During its development the diaphragm incorporates or surrounds the contents of the dorsal mesentery—the foregut, the aorta, and the inferior vena cava (See also p 772 and Fig 374.)

Classification of Congenital Hernia of the Diaphragm.—The types are (1) posterolateral, (2) anterior, and (3) hiatal. Commonly the *posterolateral hernias* represent a persistence of the pleuroperitoneal canal in which there is free communication between the pleural and abdominal cavities. Less frequently the defect has been bridged by the serosal layer so that the hernia presents with a peritoneal sac. A congenital weakness or defect in the diaphragm anteriorly at its attachment to the sternum gives rise to a *retrosternal hernia*. These hernias may or may not present with a peritoneal sac. Rarely the defect also involves the diaphragmatic portion of the pericardium so that the herniation is into the pericardial sac. *Congenital hernias of the esophageal hiatus* may present with or without a peritoneal sac. The hiatus may be abnormally large and allow the stomach to herniate through the opening with a sac of peritoneum, which rarely may contain intestine. The diaphragm and the stomach both develop considerably cephalad to their final locations. If there is a disproportionate migration caudad, a portion of the stomach may develop above the diaphragm to give rise to a thoracic portion of stomach or what has been called a congenitally short esophagus. This type of anomaly may show a persistence of a segmental blood supply to the thoracic portion of the stomach from the aorta.

Clinical Features.—Symptoms are referable to the respiratory, circulatory, and digestive systems, and the severity will depend on the amount of abdominal contents filling the thorax. In some infants respiratory embarrassment requires prompt emergency treatment. Persistence of episodes of dyspnea and cyanosis will suggest the condition. Repeated pulmonary infections with failure to thrive is sometimes part of a prolonged history. Vomiting may be present. There may be a lag of the affected hemithorax with or without audible bowel sounds. The abdomen appears scaphoid. Plain films of the chest establish the diagnosis, and the use of radiopaque materials in this examination is unnecessary and contraindicated.

The hiatal hernia may cause symptoms in infancy. It should be suspected where there is persistent vomiting, particularly if the vomitus

is coffee ground in nature or frank hematemesis occurs. A definite diagnosis can be made only by careful x-ray examination and the demonstration of a portion of the stomach lying above the diaphragm. To differentiate this from *chalasia* or cardiac incompetence, gastric rugae must be demonstrated above the hiatal opening. Unless treated early, children

Fig. 415.—Posterolateral diaphragmatic hernia. Plain film of the chest and abdomen showing bowel in the left thorax displacing the heart and mediastinum to the right. The abdomen has decreased bowel shadows.

showing regurgitant symptoms will develop the complication of esophageal stricture. The presence of esophagitis or stenosis must be excluded by x-ray and esophagoscopy examination.

Treatment.—Surgical repair of the defect of the diaphragm after reduction of the hernia

Repair of hiatal hernia is approached from above through a left thoracotomy. The technique used is that described by Allison, which restores the action of the diaphragmatic crura at the esophagogastric junction.

Fig 117—Hiatal hernia. A portion of the cardia of the stomach is above the diaphragm. There is an accompanying secondary stenosis of the esophagus.

WRINGER INJURIES

(See also Chapter 39)

With the decrease in the number of hand-operated clothes wringers and the popularity of electrically operated roller type wringers, the inquisitive child has become the victim of the *wringer injury*. It is our impression that with the advent of spin-dry and vacuum type clothes wringers on washing machines, these injuries are decreasing in frequency, but they still present a problem in a children's hospital.

The Injury.—The injury is almost exclusively confined to the upper extremity and may extend from the finger tips to the axilla. The severity depends upon the tightness of the rollers, the size of the arm, the duration of time the arm is between the rollers, and the length of the arm which is crushed. The injury may be intensified by the rollers being held up by an elbow which is maintained at right angles or by the parent attempting to extract the child without releasing or stopping the rollers. This may result in increased abrasive action in the antecubital fossa, the whole length of the arm, or damage to the shoulder joint or brachial plexus. An ipsilateral type of traumatic asphyxia has been seen on two occasions.

These injuries are likely to be misjudged by the uninitiated. Most wringer injuries are seen shortly after the accident and may appear deceptively benign. There may be slight swelling, ecchymosis, and minor abrasions, most marked in the antecubital fossa or axilla. If the thumb is abducted when the fingers are caught there may be an avulsion type laceration at the base, but fractures occur in only 1% of cases and are usually not displaced. All patients should be x-rayed. These injuries may look worse in 48-72 hours than on initial examination.

Treatment.—Because in the injuries seen early the initial treatment is so important, these patients are admitted to hospital with the exception of the obviously minor ones where rollers have been under little tension and the extent of crushing limited peripherally. The involved tissue should be cleansed with a bland detergent (aqueous Zephiran) and the ecchymotic and abraded areas covered with petrolatum gauze, over which a crimped roller gauze bandage is wrapped from finger tips to beyond the proximally crushed area. This should be covered with a cotton crepe bandage and well reinforced with 1" adhesive tape. The arm should then be elevated. In 24 hours the arm should be redressed with sterile precautions, and subcutaneous collections of blood aspirated or released through cutaneous incisions. Recently, intramuscular trypsin, streptokinase, and streptodornase have found a place in the treatment. The above therapy prevents subsequent skin loss in questionable areas, but where skin is lost it should be re-

placed by means of a Thiersch graft. When collections of serum and blood occur, systemic antibiotics should be administered. Skin contractures in the axilla and antecubital fossa should be anticipated and immobilization with the arm in abduction and the elbow in extension instituted. Lesions seen early and treated adequately leave little disfigurement. Those seen early and inadequately treated, or seen several days or weeks after injury, may show contractures, disfigurement, and limitations of function.

Chapter 31

Genitourinary System

John T MacLean, M.D

In genitourinary surgery it is essential that fundamental facts be recognized as such. These facts, combined with experience, provide a basic concept of the subject. It is for this reason that the various facts will be presented under seven main divisions, and these in turn will be applied to each area, e.g., kidney, bladder, etc. Following are the main divisions:

- 1 Anatomy and embryology
- 2 Normal physiology
- 3 Congenital abnormalities
- 4 Infections
- 5 Tumors
- 6 Trauma
- 7 Foreign bodies

Pyogenic infections, tuberculosis, and calculi will be discussed separately.

A carefully elicited history, physical examination, and urine analysis are often as valuable as the most expertly performed instrumental investigation.

A method of eliciting a history and examining a patient is as follows:

On admission to hospital:

- a Complete history
- b Urinalysis and blood count
- c Kidney function tests (PSP and NPN)
- d Roentgenograms and cystoscopy if indicated

Outline of History or Case Report

- 1 Chief complaint
Secondary complaints in order of importance

- 2 History of present illness; onset, giving symptoms in chronologic order as much as possible, looking for points in history referable to the different systems in order, as in the physical examination

Frequency:

- Day, night, on exercise
- Effect of cold or dampness
- Duration of symptoms

Pain:

- Site of pain
- Radiation to loin, genitalia, bladder, perineum, or penis
- Character—sharp—dull—aching, throbbing, requiring morphium
- Duration
- Number of attacks

Hematuria:

- Color and character: bright red clots—old or new
- Time of appearance—before, during, or after urination
- Following exercise or intercourse
- Duration

Dysuria:

- Time: on exercise, before, during, or after urinating
- Radiation to penis or elsewhere
- Duration

Alteration of urinary stream:

- Gradual or sudden narrowing of stream
- Retention of urine, complete or incomplete
- Number and duration of attacks
- Catheterization or other instrumentation employed

GENITOURINARY SYSTEM

Hesitancy in onset; force

If the facts do not appear in the history, note the absence of:

- a Hematuria
- b Passing of sand, gravel, or calculus
- c Chill
- d Fever

Physical examination

- a General
- b Local—genitourinary system

Kidneys

On examination note.

- a Tenderness in costolumbar angle
- b Kidneys palpable (bimanual examination)
- c Tenderness of kidney to palpation
- d Mass in renal region—description of size, extent, and mobility; ballottable or movable into loin; describe what you see, feel, and perceive, note any tenderness, rigidity, or splinting of the muscles of the anterior abdominal wall in the renal region

Ureters.

Examine for tenderness along course of ureters

Describe site and extent of tenderness and any masses palpated

Bladder and urethra

Inspect suprapubic area, describe visible masses as to size, shape, and extent, and by palpation any tenderness present, the consistency of any mass, and whether it is indurated or not, define the exact area of the mass by percussion

Urethral meatus.

Inspect meatus for size, discharge (smear), evidence of acute or chronic inflammation, indurations (meatal chancre)

Examine by external palpation the course of the urethra from the meatus to its disappearance in the perineum, note indurations and fistulas

Explore the urethra with soft rubber catheter (Fr No 14)

Note any obstruction found, the site, and whether it can be passed

Use gentleness at all times so as to avoid making a false passage

Record residual urine and bladder capacity in milliliters or ounces

Penis

Examine for scars, evidence of inflammation, rash

Scrotum.

Inspect for evidence of inflammation, induration or eruptions; describe any masses felt, their consistency, transmission of light, impulse on coughing, and whether they extend into the inguinal canal

Testes:

Describe size, consistency, induration, and whether any inflammation is present; note if testicular sensation is normal

Epididymes.

Describe size, consistency, tenderness

Vasa.

Describe indurations, nodules, tenderness

Venu of pampiniform plexus:
Varicocele, note if any present

Rectal examination:

- a Note if sphincter tone is normal
- b Describe prostate as to size, shape, consistency, nodules, fluctuation, and fixity to surrounding tissues
- c Carcinoma of rectum—note whether present or absent

Seminal vesicles.

Palpate for induration, nodules, tenderness

Laboratory Work

Routine on admission

- 1 Routine specimen of urine gross appearance, specific gravity, pH; sugar, albumin and microscopic examination
- 2 PSP renal function
- 3 Wassermann
- 4 NPN
- 5 Creatinine
- 6 Red and white counts, hemoglobin

Bacteriologic examination of urine specimen:
Sterile specimen for culture

Prepare culture smears, including methylene blue, Gram's stain and Ziehl-Neelsen

Urethral discharge

Smears: methylene blue
Gram's stain

Prostatic fluid

Microscopic
Smear methylene blue
Gram's stain

Dark-field examination:

Serum from sores; puncture of inguinal nodes

Other Procedures Including Operative Procedures**Intravenous Pyelogram Series****Cystoscopy**

Urethral urine specimens for

KIDNEYS**Anatomy**

Surface Anatomy.—The kidneys can be marked out on the surface of the body by first drawing the vertebral column and then

3rd and 4th lumbar vertebrae. The left kidney is very slightly higher than the right.

The ureter is marked out by a line drawn from the hilus of the kidney to the pubic tubercle.

A capsule of fat surrounds each kidney, and it in turn is enclosed between two fibrous layers derived from the fascia transversalis. The anterior layer is continuous with that of the opposite side and therefore passes in front of the inferior vena cava and the aorta. The posterior layer passes behind the kidney to the vertebral column. Above, the two layers unite

Below, the two layers are open. In nephroptosis, the kidney descends between these two layers. A perinephric abscess likewise extends downward upon the psoas muscle between these two layers. Nephroptosis may be corrected by stripping the capsule off the upper half of the kidney and attaching the lower pole to the 12th rib. It may also be corrected by suturing the anterior layer of the perinephric

fascia to the posterior abdominal wall, thereby forming a basket under the kidney.

Venous blood from the three paired glands on the right side (adrenal, kidney, and testicle) empties separately into the inferior vena cava; on the left side, that from all three into the renal vein. The right adrenal is covered by the "bare area of the liver." The lymphatics from the right adrenal empty directly into the portal

Anterior Relations

Posterior Relations

Fig 419—Anterior and posterior relations of kidneys

system. Those of the left side are connected with the lumbar nodes and pass downward to the groin and aortic nodes and upward to the deep cervical nodes and the skull

Embryologic Development of Kidney.—In the human being there are three stages of development of the kidney. The pronephros, which develops during the 2nd week of

pronephros and development of the mesonephric tubules occur simultaneously, the latter replacing the former.

At a later date the metanephros develops and becomes the permanent kidney. The excretory portion is developed from the caudal end of the nephrogenic cord (at the level of the 1st and 2nd sacral segments).

Fig 420—*Perirenal fascia* The adrenal gland is medial to section shown

embryonic life on each side of the vertebral column, forms the wolffian body, the caudal portion of which is tubular and extends distally to connect with the cloaca. About the 3rd week of embryonic life, degeneration of the

The ureteric bud arises from the postero-medial wall of the mesonephric duct and eventually forms the entire tubular collecting system. The cranial end of the ureteric bud enlarges, comes into contact with the meta-

nephros (excretory portion) which forms a cap around it, and then by a series of subdivisions forms the major calyces which divide to form the minor calyces. Thus each major calyx and in turn each tubule has a cap of metanephric tissue which becomes more highly differentiated into excretory glomeruli and convoluted tubules.

nution of the body curvature during development. During ascent of the kidneys their intrinsic blood vessels receive their blood supply from lateral splanchnic stem arteries which arise from the aorta at increasingly higher levels until the final renal artery is reached. Failure of ascent results in congenital pelvic kidney and abnormal vascular supply.

Fig. 121.—Retrograde pyelogram with presacral air insufflation, showing cyst at upper pole of right kidney, confirmed at operation.

Congenital Anomalies of the Kidneys

Polycystic Kidneys.—The renal glomeruli may, in part, fail to join the collecting tubules. If such closed glomeruli secrete urine, cysts are formed. Marked degrees of this condition give rise to congenital polycystic kidney. Minor degrees account for isolated or solitary cysts.

Congenital Pelvic Kidney.—During its development, the metanephros undergoes a relative change of position which is usually called the "ascent" of the kidney. This is partly the result of cephalad growth of the ureter and blastemal cap but is due in part also to dimi-

Aberrant Renal Arteries.—These are the result of the persistence of the blood supply from lower levels than normal.

Horseshoe Kidney.—This is due to fusion of the lower poles of the kidneys during their ascent.

Double Ureter and Triple Ureter.—These are due to early division of the ureteric bud. Double ureter may be either unilateral or bilateral, complete or incomplete.

Fetal Lobulation.—This may persist in adult life.

Congenital Absence of One Kidney.—This is the result of the failure of the mesonephric

duct (wolffian duct) to produce a corresponding renal bud

Aplastic or Anaplastic Kidney.—This is due to failure of the metanephrogenic blastema to develop

Rotation of the Kidney.—This may be (1) absent (nontotation), (2) incomplete, (3) recessive, (4) reversed

The malformation of the kidney, as such, rarely causes trouble, unless it is complicated by secondary pathologic changes. This finding has been supported by the large number of anomalous kidneys discovered at autopsy in patients who were urologically asymptomatic during life

Only 17% of individuals who have a congenital anomaly reach adult life without de-

Fig. 422 —A, Intravenous pyelogram at 2 hours showing retention of dye in left renal pelvis and upper ureter due to obstruction at this level
B, Aortogram showing that the obstruction is due to an aberrant renal artery crossing the ureter to the lower pole of the left kidney. This was confirmed at operation. An intrinsic lesion was also found in the ureter, as is frequently the case

Symptoms in the Congenital Anomalies

The symptoms are listed in Table 30

	PERCENTAGE	APPROXIMATE FRACTION
Asymptomatic	17%	1/5
Pain	79%	4/5
Frequency	32%	1/2
Hematuria	25%	1/4
Calculi	10%	1/10
Gastrointestinal	32%	1/3

veloping symptoms referable to the malformation. It would seem to be the rule rather than the exception for the patient with an anomaly to develop symptoms that soon bring him to the urologist. Approximately 30% will have symptoms referable to the gastrointestinal tract.

Practically any urologic symptoms may be encountered in individuals with congenital anomalies. In most instances, the symptoms

Valve in ureter		--	--	4 cases reported
Aberrant vessels	47	9.98	1 392	1 313

are due to acquired disease. There are many cases, however, in which there is no evidence of renal or ureteral disease, but the complaints are renal or ureteral in location. The symptoms may be produced by the following:

1. Irritation of adjacent nerves
2. Increased peristalsis of a small, asymmetric portion of the kidney pelvis
3. Relative narrowing of the lumen at the point of bifurcation and poorly coordinated ureteral peristalsis
4. Physiologic hypertrophy on the normal side, or in the solitary kidney itself

Gastrointestinal symptoms may be produced by a distended renal pelvis sending impulses through the renal digestive reflex arc via the celiac plexus.

The associated pathologic processes encountered in congenital anomalies are due to malposition, malrotation with ureteral obstruction, and resultant hydronephrosis. Infection occurs in 80% of cases. Almost every known type of secondary renal disease has been found in anomalous kidneys. The commonest associated pathologic findings are pyelonephritis (60%), hydronephrosis (45%), and calculus (20%).

Fig. 423.—Mesonephric and metanephric tubules in the embryo showing development of collecting system (After Shikunami.)

Thirty per cent of all the patients with a congenital anomaly of the urinary tract will require a major operative procedure, and of these, 50% will require a nephrectomy

Physiology of the Kidney

Renal Circulation.—Each kidney is supplied by a renal artery derived from the aorta. The artery enters the hilus of the kidney between the renal vein which is anterior and the

(intralobular arteries) are given off which supply the cortex, while other branches extend downward into the medulla.

The veins accompany the arteries and form the same pattern. Each renal vein empties into the inferior vena cava.

It is now considered that there are three possible circulations within the kidney. The first is that just described and represents the normal circulation. The second, or inner, circulation, as described by Trueta and his asso-

Fig. 424—Congenital abnormalities of the kidney and ureter (Modified after Grant)

renal pelvis which is posterior. Upon entering the kidney, or just prior to entry, the artery divides into several branches. These branches, in turn, give off interlobar arteries which run radially between the pyramids to the zone between the cortex and medulla, where they branch to form the arcuate arteries which run in a series of arcades between the two zones. From the arcuate arteries radial branches

ciates, consists of the passage of blood through the interlobular artery, the glomeruli lying in the deepest zone of the cortex (juxtamedullary glomeruli), arterial components of the vasa recta in the medulla, the venous components of the vasa recta, and the interlobular vein. Trueta and his associates claimed that during conditions of stress, blood might be "shunted" through this inner circulation, re-

sulting in blanching and relative ischemia of the cortex. There is no proof to date that this occurs clinically.

The third circulation within the kidney has been postulated by Barrie. He has described smooth muscle bundles which run longitudinally and parallel with the arcuate arteries, but on only one side of these arteries. They branch when the arteries branch, but are not continued onto the cortical arteries. Barrie has

believed that this mechanism is not found in normal kidneys but only in kidneys that have become diseased.

Glomerular and Tubular Function.—Renal function can be adjusted to meet the varying chemical demands placed upon it. By this means the composition of body fluids is maintained at levels consistent with normal cellular activity. Patients with impairment of renal function can maintain well-being only as long

Fig. 425 Renal circulation

found a mesh of sinusoids or vacuoles in these muscle fibers. The sinusoids at one end have open communications with the arteriolar coil and at the other end drain into one of the larger veins. The function of this system is unknown, but Barrie believes that it may be regarded as an arteriovenous shunt, which acts as a decompression mechanism when the arterial circuit is overloaded. Barrie further be-

lieves that this mechanism is not found in normal kidneys but only in kidneys that have become diseased.

as they can be protected from stresses that tend to seriously alter the body chemistry. The normal volume of renal blood flow is approximately 1,000 ml. per minute (one-fifth of the cardiac output), so that in 5 minutes the total blood volume has passed through the renal circulation

Filtration pressure is normally 25 mm. Hg. It is the net effective pressure of two opposing

forces. On the one side of the scale is a positive pressure of 75 mm Hg within the capillaries, which tends to force water out of the capillaries. Opposing this there are pressures that tend to prevent filtration, as shown in Table 31.

Glomerular filtration ceases and anuria develops when the systolic blood pressure drops below 60 mm Hg. If hypotension persists for only a short while, the process may be reversed, but if prolonged, it becomes irreversible.

out the operation. In most cases an almost ischemic operative field is obtained. They regard the hypotension as perfectly harmless. They state that at pressures below 75 mm Hg, "secretion of urine is much diminished and may even cease, but while effective ventilation with oxygen is maintained as in the technique described, viability of the renal epithelium is not endangered when the systolic pressure rises to the level necessary for filtration, secretion of urine starts." In their series of 44 patients, 3 showed a reduction

TABLE 31

POSITIVE PRESSURE FAVORING FILTRATION	PRESSURES OPPOSING FILTRATION	NET EFFECTIVE FILTRATION PRESSURE	FILTRATE
75 mm Hg derived from arterial side	1 Osmotic pressure of plasma proteins, 30 mm Hg 2 Interstitial pressure, 10 mm Hg 3 Pressure necessary to move fluid down tubule, 10 mm Hg	25 mm Hg	120 ml of fluid per minute in tubule, all except 1 ml of which is reabsorbed by the tubule

Fig 426—Tubular secretion and reabsorption

The work of Griffiths and Gillies of Edinburgh directly opposes this concept of "filtration pressure" which has been held for many years. They produced a total sympathetic block with the use of intravenous Pentothal and a spinal anesthetic of 150-250 mg. of procaine which is allowed to extend up to and involve the first thoracic area. The blood pressure drops off to zero and is unrecordable through-

in the output of urine during the first 36 hours after operation.

Tubular Secretion and Reabsorption.—The glomerular filtrate is identical in composition to that of blood plasma without the protein. It therefore follows that to alter the composition of the filtrate to what is eventually excreted as urine, the tubules have three main functions

1. Reabsorption of very large quantities of water. Of every 125 ml of filtrate formed every minute, 124 ml are reabsorbed (Homer Smith).

2. Secretion of creatinine, ammonia, potassium, and hippuric acid

3. Reabsorption of certain threshold substances necessary to maintain the chemical equilibrium of the body, including acid-base balance. There is some difference of opinion as to the exact amounts reabsorbed, but the figures given by Allen appear acceptable. Water is almost completely absorbed, glucose entirely, sodium and chlorides about 98%, and potassium approximately 92%.

One should note that the entire function of the remainder of the urinary tract (from the tip of the pyramids onward) is to conduct the urine to the exterior (Davis). If there is obstruction to the normal outflow of urine, the brunt of the back pressure destructive changes eventually occur in the kidney so that urea, creatinine, and such may be retained in excess (azotemia), while other substances such as sodium, chloride, and potassium may be lost in excess due to lack of normal reabsorption. The resultant chemical imbalance may prove fatal.

Nerve Supply of Kidney, Pelvis, and Ureter.—The kidney capsule is supplied with sympathetic nerve fibers from T12 and L1. Likewise the pelvis and ureter have a sympathetic nerve supply from the T11 and 12 and 1st lumbar segments. In the latter case the autonomic ganglia are situated in the adventitia of the ureter. So far as is known, the parenchyma of the kidney has no nerve supply. Overdistention of the renal pelvis, or back pressure and distention of the whole kidney, with consequent stretching of the capsule, causes pain. However, the parenchyma may be completely destroyed as in tuberculous caseation, without pain, since the parenchyma lacks a nerve supply. Parasympathetic fibers from the vagus enter the kidney, but their function is unknown.

The renal plexus which surrounds the renal artery consists of an intricate network of nerve fibers derived from the aorticorenal ganglia, middle and inferior splanchnic nerves, inter-

mesenteric nerves, and fibers from the lumbar sympathetic chain. Surgical stripping of the renal artery, as sometimes carried out in selected cases of hypertension, is usually not a complete denervation.

The origin of the impulse which initiates ureteral contraction is obscure. Some workers believe that the impulse originates in the central nervous system. Others believe that the ureters can function automatically and initiate their own muscular contractions. Most agree, however, that the usual stimulus for ureteral peristalsis is the production of urine by the kidneys and consequent distention of the ureteral wall. Peristalsis is increased by increased excretion of urine, by increased intra-abdominal pressure, and by ureteral obstruction.

Lymphatics of the Kidneys.—There are three sets of lymphatics associated with the kidneys: (1) The superficial group of lymph channels lies in the superficial or perinephric fat surrounding the kidney. (2) The subcapsular group lies beneath the capsule. (3) The third or deep group of lymphatics lies within the substance of the kidney, surrounding the tubules and blood vessels in the interstitial tissue. They drain into larger channels at the hilus of the kidney and empty into adjacent aortic lymph nodes. They all intercommunicate freely, thus assisting the spread of infection through the kidney.

In retrograde pyelography, injection of successive amounts of contrast media into the renal pelvis may cause a backflow of the dye into the deep (intrarenal) lymphatic system or veins. This is known as *pyelovenous backflow*.

Chyluria.—Normally the fat particles which enter the intestinal lymphatics give the lymph fluid a milky appearance (chyle). This passes upward through lymphatic channels and eventually into the main lymphatic duct. In some conditions such as filariasis, the main lymphatic channels may become occluded. The chyle backs up and may be forced by ever-mounting pressure into the deep lymphatics of the kidney and thence by further pressure into the renal pelvis, where it is excreted in the urine. This is known as *chyluria* and is the reverse process of pyelovenous backflow.

Orthostatic Albuminuria

Orthostatic albuminuria is a condition in which albumin is found in the urine without any pathologic condition in the kidneys. It is usually due to lordosis causing some pressure on the renal vein, resulting in delayed emptying.

Orthostatic albuminuria may be tested for by producing exaggerated lordosis in one of two ways: (1) by placing a pillow under the small of the back when the patient is lying flat, or (2) by having the patient bend backward 10 degrees for 10 minutes while standing with his hands on hips.

The following criteria are required before a diagnosis of orthostatic albuminuria is made:

- 1 No past history of renal or cardiovascular disease
- 2 No elevation of blood pressure
3. No WBC, RBC, or casts in the urine, except intermittently and in small numbers
4. Normal kidney function (PSP, urea clearance test, urine concentration tests)
- 5 Normal blood chemistry (NPN, urea clearance, total protein, normal albumin-globulin ratio)
- 6 Negative plain x-rays and normal intravenous pyelograms
7. Absence of albumin in the urine secreted when in the horizontal position

Hydronephrosis

Hydronephrosis is a dilatation of the renal pelvis, with stagnation of urine caused by an obstruction to the outflow of urine. The obstruction is nearly always mechanical, but on rare occasions may be due to neurogenic dysfunction. Hydronephrosis may affect one or both kidneys, it may be congenital or acquired and may be infected or not infected.

Primary Renal Atrophy.—Sudden complete obstruction of the ureter is thought by some to produce primary atrophy of the kidney without a preceding hydronephrosis. This belief is, however, not borne out by either experimental or clinical observation. It occurs so rarely that it may be disregarded.

Hydronephrosis With Secondary Renal Atrophy.—The usual sequence of events following obstruction to the outflow of urine

is as follows. Dilatation of the renal pelvis or renal pelvis and ureter above the site of the obstruction occurs, whether this is at the ureteropelvic junction, in the ureter, or at the entrance of the ureter into the bladder. As the back pressure is increased, the walls of the ureter and pelvis become progressively distended. Urine continues to be formed. Absorption of urine from the pelvis occurs while the kidney still continues to secrete urine. The contents of the hydronephrotic sac thus change continuously. Absorption of the fluid in the hydronephrosis is thought to take place either through the tubules or by pyelovenous backflow, or by both.

Eventually the combination of increased intrapelvic pressure, renal ischemia, and disuse results in degeneration and atrophy of the kidney.

Hydronephrosis develops more rapidly in a high obstruction than it does in a low obstruction. The rate of urine formation, however, remains the same whether fluids are forced or withheld completely.

Symptoms.—The symptoms are those of the underlying pathologic process, i.e., obstruction. There may be no symptoms at all or a dull ache in the back. If the hydronephrosis becomes infected, there will be chills, fever, and frequently pus in the urine.

Treatment.—Remove the underlying cause of the hydronephrosis if possible. If this is not possible, or if the disease in the kidney is far advanced, remove the kidney.

Anuria

Anuria is the cessation of urine formation. Oliguria is decreased secretion of urine. The causes of anuria are listed below. The post-renal causes are due to obstruction to the outflow of urine. They are usually classified under anuria because no urine is obtained. In these cases urine is formed, so that it is not a true anuria.

Causes of Anuria

I. Prerenal (Circulatory)

1. Occlusion of the main vessels of both kidneys by embolism or by the external pressure of a tumor

2. Reduction of blood volume due to
 - a Dehydration, e.g., diarrhea, vomiting, excessive perspiration
 - b Hemorrhage
 3. Retention of fluids in the tissues (generalized edema)
 - a Advanced cardiac decompensation
 - b Retention of salt in the tissues
 4. Endocrine form—due to dysfunction of the pituitary, thyroid, or adrenal gland—these forms rare
 5. Low blood pressure, as in shock
 6. Reflex anuria—or inhibitory form
 - a Inhibition of uninvolved kidney by obstruction in opposite kidney
 - b Vascular spasm of main vessels following splanchnic stimulation as in abdominal surgery, distention, etc.
 - c Peripheral irritation, e.g., passing sounds, catheterization, ureteral calculus, etc
 - d Anesthesia, especially spinal
 - e Severe painful stimuli
- II. Renal—Intrinsic Renal Disease—(Excretory) (Occur on the basis of inadequate secreting renal tissue)
- 1 Acute infectious nephritis, glomerulonephritis, suppurative nephritis
 2. Extensive destruction of kidney tissue bilaterally, e.g., advanced tuberculosis, polycystic kidney disease

Fig 427.—Flow of blood through the artificial kidney. The blood is forced by arterial pressure through Tygon tubing into the dialyzing membrane wound on the reel. It is worked to the left by the rotation of the reel. The rinsing fluid continuously bathes the membrane. The blood as it leaves the machine is pumped through an air trap and clot filter, back to a vein. A shunt line is provided to by-pass the machine. There is also provision for transfusion equipment.

3. Acute nephrosis, e.g., poisoning by heavy metals, mercury, bismuth, arsenic, lead
4. Acute toxic nephritis
 - a. Toxic products from damaged liver
 - b. Pre-eclamptic toxemia
5. Post-partum cortical necrosis
6. Following removal of solitary kidney

III. Postrenal—Obstructed Outflow of Urine (Eliminatory)

- 1 *Intrinsic*—blockage of one or both ureters by blood clot, calculi, stricture, neoplasm of pelvis or ureter, sulfonamides, tumor of bladder, enlargement of prostate
- 2 *Extrinsic*
 - a Accidental injury or ligation of ureters during gynecologic or other operations
 - b Retroperitoneal growths and malignant pelvic tumors
- 3 *Composite or Mixed* (Includes those cases where more than one of the above factors are present)
 - 1 Injuries to kidney and ureter
 - a Injury or avulsion of a single kidney
 - b. Bilateral renal rupture
 - 2 Lower nephron nephrosis—which may occur after crushing injury to muscle, non-traumatic muscular ischemia, burns,

transfusion reactions with incompatible blood, heat stroke, malaria, toxemia of pregnancy, alkalosis, sulfonamide anuria and following transurethral prostatic resection

Treatment of Anuria

Treatment of the prerenal and renal causes of anuria:

1. *Prevention*—maintain an adequate blood volume and adequate blood pressure.
2. *Active treatment*—try to restore the blood pressure and blood volume to normal by means of blood transfusions, vasoconstrictors, and adrenal cortical extracts. Renal decapsulation may be indicated

Treatment of postrenal causes of anuria: Remove obstructive cause if possible.

Treatment of lower nephron nephrosis: In lower nephron nephrosis the kidney normally tends to recover spontaneously between the 5th and 9th day of the disease. During this period it is important to limit fluids to 1,500 ml. daily, i.e., the amount lost through respiration and perspiration. If the anuria persists and the kidney fails to recover spontaneously, the artificial kidney may be used to wash the waste products from the blood

TABLE 32
TREATMENT OF LOWER NEPHRON NEPHROSIS

FIRST 24 HOURS (CONSERVATIVE TREATMENT)	AFTER 24 HOURS	5TH TO 9TH DAY
<ol style="list-style-type: none"> 1. Treat shock if present 2. Good nursing care 3. Posture, especially for good drainage of chest 4. Indwelling urethral catheter to collect all urine 5. Antibiotics 6. Digitalization if necessary 	<ol style="list-style-type: none"> 1. Cystoscopy with retrograde pyelography to ensure accurate diagnosis 2. Limit fluid intake of 1,500 ml of 5-10% glucose in water, plus an extra amount equal to the amount of urine excreted if any 3. Do not give sodium chloride during this period 4. Maintain electrolyte balance, correct acidosis by giving ½ molar sodium lactate intravenously or 1 ½% sodium bicarbonate 	<p>This is time that spontaneous recovery most likely to occur; if, however, patient becomes excessively toxic, treatment with artificial kidney recommended</p>

DURING RECOVERY

(when diuresis has become established)

1. Increase fluid intake beyond basic 1,500 ml daily, by an amount equal to amount of urine excreted in 24 hours
2. Measure 24-hour output of chloride in urine and replace this gram for gram
3. Frequent blood chemistry estimations; compensate for any deficiencies present

Bilateral Diffuse Cortical Necrosis

This lesion is defined by Duff and Moore as a pathologic entity of unknown cause manifested by extensive uniform necrosis of the cortex of both kidneys. There are two theories of origin: (1) that it is due to toxins, as in pregnancy; (2) that it is due to ischemia causing vascular occlusion. Clinically there is oliguria, anuria, and pain, usually epigastric, radiating along the ureters. Edema of the dependent parts occurs. The outcome is usually fatal, however, a very few patients do recover.

Sulfonamide Anuria

The use of the sulfonamides either as a prophylactic or therapeutic measure entails some risk.

The sulfonamides are excreted by the kidneys, being concentrated as much as three hundred times in the urine by tubular absorption. There is no relationship between the blood level of the sulfonamide and the patient's ability to tolerate the drug.

Any patient receiving the sulfonamides should be given enough fluids to ensure a 1-hour urinary output of at least 1,500 ml. Sodium bicarbonate may be given along with sulfonamide.

Sulfonamide anuria can be prevented by limiting the administration of sulfonamides and controlling the pH of the urine. The blood and urine levels of the drug, the presence of microscopic hematuria, and the possibility of sensitivity to the drug should all be borne in mind when using this type of therapy.

When anuria does occur, treatment should follow a definite plan. The drug must be discontinued. Cystoscopy is done to exclude the existence of mechanical obstruction to the drainage of urine and to wash each kidney pelvis, thereby removing any crystals and blood clot present. If mechanical obstruction of the ureter exists, and it is impossible to catheterize either renal pelvis, pyelotomy must be performed.

Renal Hypertension

(See Chapter 19, Liver and Portal Hypertension.)

Renal Rickets

Renal rickets is a disease of childhood characterized by the symptoms of polyuria, polydipsia, retardation of growth, deformity of growth, and delayed sexual development. A genu valgum develops. With the increased softening of the metaphyses, extreme degrees of distortion and deformity may be produced.

The kidneys show some degree of deficiency which may be pronounced as the disease advances. Chronic pyelonephritis is frequently present and calculus formation is a frequent complication. The specific gravity of the urine is fixed at a low level.

There are two types of bone changes which may occur:

1. Rachitic changes at the ends of long bones.
2. Generalized osteoporosis with loss of distinction between cortex and medulla.

The blood phosphate is elevated and the blood calcium lowered.

The cause of renal rickets is unknown. One theory is that it is primarily a renal disease, due to inability of the kidney to excrete an adequate amount of phosphates. A second theory is that renal rickets is an endocrine disease, caused by primary overactivity of the parathyroid glands with or without associated pituitary dysfunction.

There is no known treatment for this disease. Death from renal failure usually occurs before the age of 20 years.

RENAL INJURIES

The kidney is protected by its mobility and retroperitoneal position. Injuries are caused by external violence, such as a fall, kick, or blow on the back or side, by crushing injuries, or by penetrating wounds. Eighty per cent are due to blows on the back or side. The kidney responds like a ball of fluid to the force of an impact, transmitted in all directions.

The pathologic changes that occur are shown in Fig. 428 and are tabulated as follows:

1. Tears of the fatty capsule only. Hemorrhage into the perirenal tissues may be absorbed, organized, or encysted.
2. Contusion of the kidney. This is not serious unless it becomes infected.

3 Rupture of the parenchyma, usually posterior surface, with resultant pulping of the kidney. Hemorrhage may be marked or even fatal. Hematuria is always present. Nephrectomy may be considered.

4. Rupture of the parenchyma and capsule. The hemorrhage is greater than when the capsule is not torn.

5. Rupture of the parenchyma, capsule, and pelvis. The vessels of the renal pedicle are usually torn, and hemorrhage may be fatal. There may be urinary extravasation with infection.

Diagnosis.—Diagnosis is based on (1) history of injury, (2) variable degree of shock, (3) hematuria, (4) localized tenderness and rigidity, (5) a palpable mass, which may or may not be present.

The foregoing changes shown in Fig 428 describe the pathologic lesion which may be present in the kidney. It should be noted that clinically the extent or degree of injury is not nearly as precisely defined. If a patient has a complete rupture of the vascular pedicle, he obviously will live only a few minutes. Consequently upon the arrival of an injured

Fig 428.—Injuries of the kidney

6. Rupture of the parenchyma with rupture of the peritoneum. This is a rare but serious type which occurs chiefly in children.

7. Rupture of the vascular pedicle and tearing of the ureter. The pedicle is sheared off. Death occurs promptly from hemorrhage.

8. Rupture of the liver or spleen may be associated with rupture of the kidney.

patient in the hospital, the immediate decision to be made is whether the injury is major or minor. The effect of the perirenal fascia in limiting the spread of the extrarenal hematoma should also be noted (Figs. 420 and 428).

Treatment.

1. *Immediate.* The following supportive measures are most important: (a) treatment of

shock, (b) adequate blood transfusion. The blood pressure, pulse, and degree of hematuria must be carefully followed.

2 If patient is recovering, (a) continue conservative treatment, (b) give urinary antiseptic daily, (c) do an intravenous series as soon as possible after the patient is out of shock. This will give an approximate idea of the degree of damage to the kidney and establish the presence or absence of the other kidneys. If the bladder is included in the x-ray films it will also show whether there is an extravasation of dye from a rupture of the

If the patient continues to improve a cystoscopic with retrograde pyelograms and a differential PSP test may be carried out several days later. The PSP test is particularly valuable for defining in legal terms the degree of damage to the kidney, and it will indicate the degree of progression of the fibrosis in the ruptured kidney (see below).

3. If condition continues to deteriorate after initial therapy, i.e. pulse rate steadily increases or blood pressure cannot be maintained in spite of continuous transfusion, (a) prepare for nephrectomy and carry out exploration of the kidney, (b) make certain the opposite kidney is present before operating—this may be done by intravenous pyelography, (c) when the kidney is exposed and attempts to control the bleeding are unsuccessful, immediate nephrectomy should be done.

Complications.—

1. Sepsis—usually prevented by giving urinary antiseptics or antibiotics
2. Secondary hemorrhage
3. Fibrosis of part or the whole kidney resulting in scar formation with partial or complete loss of function

Prognosis.—

1. Seventy per cent recover without requiring an operation, even though critically ill on admission
2. A secondary nephrectomy for a nonfunctioning kidney may be required months after the initial injury.

NEPHROPTOSIS

Nephroptosis of the kidney is descent of the kidney beyond the normal 4 cm. dia-

phragmatic excursion. Reference to Fig. 420 will indicate how this may occur. It is present in approximately 1% of men and 6% of women. It is much more common on the right side because of the weight of the liver and the fact that the renal fossa is shallower on this side. The kidney is normally held in place by the fatty capsule and surrounding fascia, the vascular pedicle, and the support supplied by surrounding organs. In a thin person, and in one in whom there is a decrease of muscle tone, the additional trauma of a twist or fall, or the added weight of an overloaded colon, may be sufficient to cause ptosis of the kidney. Ptosis frequently causes kinking of the ureter and back pressure with resultant hydronephrosis.

The symptomatology varies considerably. There may be no symptoms referable to the ptosis, but in 66% of cases there is pain in the lumbar region, due to improper drainage, which gradually increases as the day wears on and is relieved by recumbency, which permits the kidney to fall back into place and thus improves drainage. The symptoms are occasionally entirely nervous because of a reflex from the kidney through the celiac axis. The patient then complains of epigastric pain, nausea, and vomiting. In some cases the patient complains of acute attacks of violent pain like that of renal colic. These attacks are called *Dietl's crises* and are attributed to kinking of the ureter or to twisting of the kidney pedicle. The symptoms may be entirely gastric (22%), in type, the patient being irritable and easily fatigued. It is of the utmost importance to select cases for operation carefully. It is only those patients who have pain in the back, increasing as the day advances, and relieved by lying down who should be subjected to operation. The accidental finding of ptosis of the kidney without any of the above symptoms is definitely not an indication for surgery. Similarly, the emotionally unstable type of individual with innumerable complaints will not obtain a good result from nephropexy, even though the corrected anatomic position of the kidney is excellent, the patient will continue to complain of pain. Generally speaking it is advisable to treat these patients with a well-fitting elastic girdle with attached

In the patient selected for operation, nephropexy may be done by one of several procedures. Decapsulation of the upper two thirds of the kidney with a suture passed through the lower pole and tied over the 12th rib is the operation most used. The denuded area of the kidney becomes firmly adherent to the undersurface of the diaphragm, peritoneum, and posterior abdominal wall. An alternative procedure is to expose the kidney and use the perirenal fascia to form an apron, which is stitched down to the muscles of the posterior abdominal wall with interrupted sutures, thus forming a basket beneath the lower pole of the kidney. If cases are properly selected as indicated above, and if the operation is well performed, the results are excellent. The patient obtains complete relief of pain, and recurrence of the ptosis does not take place. If, however, all patients with nephroptosis are operated upon without selection, the results will not be uniformly good.

TUMORS OF KIDNEY

Tumors of Children

Wilms' Tumor (Synonym: Embryoma or Adenomyosarcoma)

Clinically, Wilms' tumor or embryoma represents 20% of all tumors occurring among children. The age incidence is from birth to 10 years, 75% occurring in the first 5 years of life. In the later decades a period when other tumors are more common, one rarely encounters a Wilms' embryoma. Sex is not a factor. These tumors are extremely malignant. With early recognition, a 5-year cure may be effected in 25% of cases. A few cases have been reported in which the patient was alive 10 years or more after nephrectomy.

Origin.—The origin of mixed renal tumors is not clear. Most observers agree that the tumors are embryonal, in that they arise in the region of the developing kidney.

Three Theories of Origin—

1. The tumor is due to inclusions of wolffian tissue which have become displaced and which persist among the cells of the developing kidney or metanephros.
2. The tumors arise from aberrant cells of the myotome and sclerotome, the apparent

mixed character being explained by the varying constituents that enter the ultimate formation.

3. The tumors are not due to inclusions from extrarenal sources, but they are true kidney, the embryonic tissue persisting and becoming metamorphosed into cellular structures of various types.

Pathology.—

Gross.—The Wilms' tumor is a large, solid, grayish white, encapsulated tumor of variegated histology. It is usually separated from the kidney by a layer of tough connective tissue. The capsule of the tumor blends with that of the kidney and with this membrane.

Microscopic.—The tumors are composed of a variety of tissues. The microscopic picture varies according to the predominating type of tissue present. In addition to simple epithelial and mesenchymal components, the presence of muscle elements indicates that tissue from the myotomes is included. The small papillary buds seen in some of the glandular components of the tumor may be abortive glomerular structures.

Signs and Symptoms.—

1. Presence of swelling in the upper abdomen—most cases.
2. Painless—usually.
3. Occasionally painful—usually late—due to pressure or to tension on peritoneum associated with weakness, pallor, fever, gastrointestinal symptoms due to bowel displacement, hematuria (10%), and hypertension.

Diagnosis.—History and signs and symptoms as above, plus deformity of the pyelograms.

Differential Diagnosis.—

1. Other kidney tumors and hydronephrosis.
2. Polycystic kidney disease.
3. Retroperitoneal tumors separate from the kidney.
4. Adrenal neuroblastoma (preoperative differential diagnosis may be impossible).
5. Splenic enlargements.
6. Tumors of liver.
7. Omental and pancreatic cysts.
8. Ovarian tumors.

Treatment.—Preoperative radiation followed by nephrectomy offers the best results.

TABLE 33
CLASSIFICATION OF TUMORS OF THE KIDNEY

A Children—Wilms' embryoma

		Solid type	{ Squamous cell carcinoma Adenocarcinoma
(c) CAPSULAR TUMOR		{ Lipoma Fibrolipoma Fibrosarcoma Liposarcoma	

the tumor usually shrinks with radiation therapy followed by radiation is an alternative method of treatment

Prognosis.—Although the tumor can be removed successfully, the likelihood of recurrence is so great that the prognosis is poor. Metastases may occur even before one suspects the presence of a primary tumor

Tumors of Adults

- 1 Tumors of Renal Parenchyma
 - 2 Tumors of Renal Pelvis
- Forms 0.5% of all tumors in adults

Tumors of Renal Parenchyma

Tumors of Epithelial Origin —

BENIGN — Adenoma

Small adenomas, varying in size from 2 mm. to 1 cm. or larger, are found occasionally at post mortem in arteriosclerotic kidneys. They occur in the form of multiple discrete, whitish nodules located just beneath the renal capsule or scattered throughout the renal parenchyma. They often occur bilaterally. Histologically, they are made up of irregular groups of epithelial cells ranged around lumina which are regular in outline. Papillary projections of epithelial cell masses into such a lumen are a

frequent observation. The epithelium, however, is present only in a single layer. The resemblance to normal renal tubules is so close as to render differentiation difficult

MALIGNANT.—Carcinoma (Synonyms: Grawitz tumor, hypernephroma; hypernephroid carcinoma).

Primary malignant tumor of the kidney is almost always unilateral.

In 1883 Grawitz proposed the theory that these tumors arise from aberrant adrenal tissue. Most people today believe that the tumor is a renal carcinoma arising either from adult tubules or from islets of nephrogenic tissue which have persisted in the renal cortex. A single renal tumor often exhibits mixed features

Gross Pathology of Renal Carcinoma (Hypernephroma).—The striking variegated yellow and red of its gross appearance result from the high lipid content of the neoplastic cells and the hemorrhages which are almost invariably present.

Microscopic Pathology.—The clear cells which are prominent in microscopic sections of these tumors bear a vague resemblance to the cells of the adrenal cortex, which led

Grawitz to believe that they were derived from adrenal rests. Many hypernephroid tumors are not composed entirely of clear cells. Granular cells and mixed cell variants are also recognized. Furthermore, not all hypernephroid tumors are malignant, and the differentiation between adenoma and adenocarcinoma is often

looking growths may metastasize widely through the renal vein. It is therefore important to examine the vessels grossly and microscopically.

Metastases.—Metastases occur by direct extension of the growth through the capsule or into the renal vein, with showers of em-

Fig 429.—Wilms' embryoma. Intravenous pyelogram showing large shadow in region of left kidney with only superior calyces filled.

difficult. The size of the tumor is not a criterion of its degree of malignancy. If there is obvious invasion of the pelvis or frank cellular anaplasia, then the diagnosis of malignancy is simple. However, encapsulated and benign-

bolus into the blood stream. Spread takes place in this manner to the lungs, brain, and long bones. Pathologic fracture of a bone may occur before the primary tumor is recognized.

Fig 432 — *A*, Retrograde pyelogram showing enlarged right kidney with compression of entire pelvis and calyces

B, Gross specimen of carcinoma of upper pole of kidney

Fig 433 — X-ray of chest showing cannon ball metastases from carcinoma of kidney.

Prognosis.—The prognosis is poor. Without surgical intervention a fatal outcome is inevitable within approximately one year. In cases seen before metastases are present, surgical removal offers a distinct hope of cure. The outcome depends upon an early diagnosis and complete removal of the tumor. In the majority of cases the disease is well advanced before the patient consults a doctor.

Connective Tissue Tumors.—

BENIGN —

1. *Fibroma.* Two forms occur, the first as small whitish nodules which rarely cause symptoms and are usually discovered at autopsy and the second as large cortical growths which produce symptoms and require surgical treatment. They are rare but may occur at any age, even in children.

2. *Lipoma.* Small multiple masses of lipoid tissue may be present beneath the renal capsule or in the cortical substance. They are rarely larger than 1 cm in diameter.

3. *Leiomyoma.* Leiomyoma is a tumor composed of plain muscle. It may have fibrous tissue mixed with it so that the tumor is in reality a fibroid and identical to a fibroid in the uterus. It rarely reaches sufficient size to produce symptoms.

Sarcomatous degeneration may occur in any of the above tumors but is rare.

4. *Hemangioma.* Hemangiomas are occasionally encountered. Unless they attain considerable size and cause pressure or other symptoms, they are of no clinical importance. Hematuria does not occur unless the tumor erodes the renal pelvis. In the differential diagnosis of essential hematuria or occult hematuria, a minute angioma which may be so small that it is easily overlooked at operation is a possibility to be considered.

MALIGNANT —

Sarcoma is very infrequent in adults. Fifty per cent occur between the ages of 40-60 years. The histopathologic structure varies considerably, but all are highly malignant and invariably terminate fatally regardless of treatment. Spindle cell sarcoma is the most common type, with fibrosarcoma, leiomyosarcoma, and other forms being very rare.

The symptomatology, diagnosis, and treatment are the same as for other parenchymal

Signs and Symptoms of Renal Tumors.—

1. *Hematuria* is the most constant finding and may be the earliest symptom except in Wilms' tumor in children, in whom a mass is usually the first sign. Bleeding is always intermittent and seldom profuse. A single hemorrhage may be followed by months or even years without recurrence.

2. *Pain* in the kidney is the initial symptom in 20% of cases and is present in a large percentage of the late cases. It may be caused by stretching of the renal capsule by the expanding tumor, or it may result from pressure by the mass on neighboring nerves, viscera, or ureter, i.e., hydronephrosis.

3. Although hematuria and pain are the commonest symptoms, loss of weight, weakness, gastrointestinal disturbances, fever, cachexia, and anemia may occur. These are usually late symptoms.

Diagnosis.—The diagnosis of renal tumor is made on (1) history, signs, and symptoms, (2) deformity shown in the pyelogram, usually a filling defect.

Prognosis.—Success in the treatment of renal tumors depends upon their early recognition. The over-all prognosis is poor.

Treatment —

1. Prompt nephrectomy with postoperative radiation is the treatment of choice.

2. In inoperable cases with considerable bleeding, Dicumarol may be given to diminish coagulation and minimize the colic caused by the passage of blood clots.

3. Ligation of the ureter may be carried out if the tumor is inoperable and the kidney is not infected.

Tumors of Renal Pelvis

In a 40-year period at the Royal Victoria Hospital, from 1915-1954, there were 207 patients with kidney tumor operated upon, of which 15 had primary carcinoma of the renal pelvis. In an 8-year period in the Department of Veterans Affairs Hospitals in Canada there were 164 patients with renal tumors operated upon or found at autopsy, of which 18 had primary carcinoma of the renal pelvis.

In the total series of 371 cases, 33 were carcinomas of the renal pelvis, giving an incidence of 7%.

CLASSIFICATION OF TUMORS OF RENAL PELVIS AND URETER

Tissue of Origin

I Epithelial

- Gross { Papillary 75%
Solid 25%

Microscopic (Whitlock, McDonald, and Cook 1954)

- 1 Papillary carcinoma, Grades 1, 2, and 3
- 2 Papillary and infiltrating carcinoma, Grades 2, 3, and 4
- 3 Nonpapillary infiltrating carcinoma, Grades 2, 3, and 4 (including transitional cell carcinoma, squamous cell carcinoma, and adenocarcinoma)

- Note 1 Structural type (i.e., papillary or non-papillary)
2 Presence or absence of infiltration
3 Cell type transitional or squamous
4 Degree of anaplasia

II Mesodermal

Benign fibroepithelial polyp

- Myoma
- Lipoma
- Neurofibroma
- Angioma

Malignant
Fibrosarcoma
Myosarcoma
Lymphoblastoma

III Endometriosis

IV Metastatic

Carcinomas of the renal pelvis arise from the epithelium which is similar morphologically to that of the ureter and urinary bladder. The epithelium of the renal pelvis is stratified and does not exhibit keratinization or cornification. It is therefore called transitional in type. Certain stimuli, such as chronic infection and stones, may cause the epithelium of the bladder, ureter, and pelvis of the kidney to cornify (leukoplakia), while under other circumstances, such as in extrophy of the bladder, cystitis, ureteritis, and pyelitis glandularis, the epithelium assumes a glandular form. These changes are precancerous conditions.

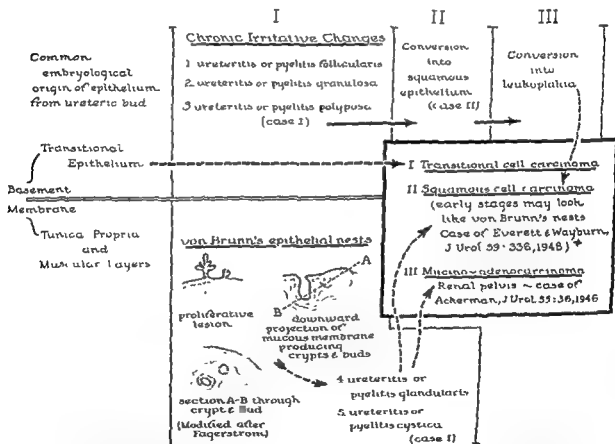

Fig. 434—Diagram showing changes that may occur in metaplasia in the urinary tract. MacLean and Fowler have reported a case of squamous cell carcinoma of the renal pelvis and one of mucinoadenocarcinoma.

(A, C from MacLean, J. T. *Brit J Urol* 26: 127-138, 1954.)

Papilloma and Papillary Carcinoma.—These tumors are usually multiple, appearing as villous growths which are very vascular and bleed easily. They may only involve a small area or be extensively distributed over the mucosa of the pelvis, ureter, and bladder.

Microscopically the papilloma consists of branching processes containing minute blood vessels, covered with many layers of transitional epithelium. The tumor cells are cuboidal or cylindrical. Round cell infiltration is present in the stroma. The structure is typical and uniform. Though usually benign, it has a tendency to become malignant. Once the tumor invades and infiltrates the submucosa and connective tissue, it becomes a true papillary carcinoma.

Hematuria is an early symptom because of the marked vascularity of the papillary processes.

Metastases occur in the ureter and bladder in over 50% of cases by direct seeding. It is

therefore imperative that the entire ureter be removed along with the kidney.

These growths may cause various degrees of hydronephrosis, depending upon the site and degree of obstruction.

Nonpapillary Tumors.—

1. *Adenocarcinoma* is a large, infiltrating, highly malignant type of tumor which metastasizes rapidly to any part of the body. It is regarded as being a far-advanced papillomatous growth which has lost its papillary character and has assumed an alveolar or scirrhous appearance.

2. *Squamous cell carcinoma* is a highly malignant tumor which has an insidious onset and runs a rapid and fatal course. It is rare

A.

B.

Fig. 436—A, Pyelogram showing catheter curled up in left lower ureter.
B, Gross specimen of case in A, showing tumor of mid-ureter

Chronic infection, leukoplakia, and calculus are frequently associated with squamous cell carcinoma of the renal pelvis and are believed to play an important role in its causation.

The squamous pelvic tumor is a grayish, indurated, infiltrating growth which extends over a limited portion of the mucosa. It is large, flat, and ulcerated, but occasionally tends toward a papillary form.

Microscopically the squamous qualities are pronounced. There is usually cornification and pearl formation. These tumors rapidly invade the surrounding structures, including the kidney. The prognosis is poor. There has been no 5-year cure reported.

Signs and Symptoms.—These are the same as in other tumors. Hematuria is the most frequent symptom.

Differential Diagnosis.—The conditions to be excluded in the differential diagnosis are renal tuberculosis, renal calculus, pyelonephritis, and tumors of the renal parenchyma.

Treatment.—Treatment is nephroureterectomy, plus the treatment of any seeding present in the bladder.

PRIMARY CARCINOMA OF THE URETER

Ureteral tumors closely resemble bladder tumors in their pathologic characteristics.

At the Royal Victoria Hospital, in the 30-year period from 1925-1954, inclusive, there were 4 patients with primary carcinoma of the ureter operated upon. In a 22-year period from 1932 to 1954, there has been one case of primary carcinoma of the ureter found in 10,223 successive autopsies.

There are two main groups: (1) papillary—more common and (2) nonpapillary.

They occur most commonly in the 4th to 6th decades and are more common in the lower third of the ureter.

Although ureteral tumors are quite similar to bladder tumors pathologically, metastases from ureteral tumors occur earlier and more

A

B

FIG. 437.—A, Ureterogram showing complete obstruction to the passage of dye beyond the level of the 3rd lumbar vertebra.

B, Gross specimen of case in A, showing solid tumor in upper ureter at site of obstruction.

frequently. This may be due to the insufficient barrier offered by the thin wall of the ureter as compared to the thick wall of the bladder and to the richer lymphatic drainage of the ureter

Signs and Symptoms of Tumors of the Ureter.—Hematuria is the commonest symptom. Pain along the course of the ureter may occur. A mass along the course of the ureter may be palpable

Diagnosis.—The diagnosis is made on the history of physical signs and deformity shown in the pyelograms or ureterograms.

Treatment.—This consists of nephroureterectomy where possible. If this is not possible, intraureteral radium or deep roentgen therapy may be used

Prognosis.—The prognosis in ureteral tumors is good if they are diagnosed early.

PYOGENIC INFECTIONS OF THE URINARY TRACT

Normally the urinary tract is sterile in both the male and the female, with the exception of the terminal 1 cm of the urethra. When infection occurs repeatedly or persists, there is usually urinary stasis due to some degree of obstruction to the normal flow of urine. The obstruction must be relieved in order to cure the infection. Where there is paralysis of the bladder, as in the paraplegic patient, repeated and recurrent attacks of infection are common.

The infection may reach the urinary tract from the following

1. Blood stream—hematogenous
2. Lymphatics—lymphogenous
3. Direct extension from other organs, e.g., abscess
4. The exterior—(a) trauma and (b) gonococcus

When the kidney is attacked, its function is impaired and the organ is permanently damaged. Infections of the skin, bone, intestine, throat, teeth, and cervix may act as foci of infection for the urinary tract.

Pyogenic infections of the urinary tract are due to invasion of the kidney, ureter, or bladder by the organism itself rather than by a toxin. The organism causes an inflammatory reaction in the interstitial tissue, whereas the toxin acts on the glomerulus producing a glomerulonephritis.

Diagnosis.—Certain criteria must be met to establish an accurate diagnosis. Pyogenic organisms must be present. Failure to examine the specimen for organisms is the commonest cause of error in diagnosis. The specimen examined should be freshly voided in the male and be a catheterized specimen in the female. It should be collected in a sterile container.

If organisms are found, they may then be assumed to come from the patient. The prognosis depends largely upon the etiology. In a male patient, if there is any doubt as to whether a urethritis may be producing the pus in the urine, a three-glass urinalysis should be done.

Three-Glass Urinalysis.—The patient is asked to void into three separate containers. The first containing 1-2 ounces represents urethral washings. The second also containing 1-2 ounces is discarded. The third specimen may therefore be regarded as truly representing the conditions in the bladder. If the first specimen shows 40 pus cells per high power field and the third specimen only 2 or 3, the patient obviously has a urethritis. If, however, the third specimen shows just as many pus cells as the first specimen, then the patient must have an infection either in the bladder or at a site higher up in the kidney.

Bacteriology.—The infecting organisms in the order of frequency are as follows:

- | | | |
|--|--|-----|
| 1 | <i>E. coli</i> (<i>Escherichia coli</i>) | 42% |
| 2 | Other gram-negative bacilli | 30% |
| Roughly 70% are due to gram negative bacilli | | |
| a | <i>Aerobacter aerogenes</i> (<i>B. coli aerogenes</i>) | |
| b | <i>Pseudomonas aeruginosa</i> (<i>B. pyocyaneus</i>) | |
| c | <i>Pseudomonas fluorescens</i> (<i>B. fluorescent</i>) | |
| d | <i>Proteus vulgaris</i> (<i>B. proteus</i>) | |
| 3 | <i>Staphylococcus pyogenes</i> | 12% |
| a | Micrococci | 8% |
| 4 | Mixed organisms | 20% |
| 5 | Other types | |
| a | Gram-positive bacilli | |
| b | <i>Streptococcus faecalis</i> (Lancefield \square streptococcus) (synonym— <i>Enterococcus</i>) | |
| c | Diphtheroids | |
| d | Gonococci (<i>Neisseria</i>) | |

The bacteriology of urinary tract infections appears to be changing. Staphylococcal infections now seem to be more prevalent than *E. coli* infections in some areas of the country.

From a clinical point of view an elaborate process of staining is undesirable and unnecessary as nearly all the bacillary infections are gram-negative and all the coccal infections, with the exception of gonococci, are gram-positive. A simple methylene blue stain is therefore adequate to determine whether one is dealing with a bacillary or coccal infection.

Following are the natural groups:

1. Pyelonephritis only
2. Groups under 15 years of age
3. Groups complicated by renal calculi
4. Associated with pregnancy
5. Cystitis only
6. Cystitis in the female associated with narrowing of the urethra
7. Associated with overgrowth of the prostate
8. Occurring in fractured pelvis, ruptured bladder, and cord bladder

Fig. 438.—Method of preparing a methylene blue stain on urinary sediment. The slide should not be made any hotter than the back of the hand can stand, otherwise the bacteria will be destroyed.

In staining, the slide is warmed over a Bunsen burner but is not allowed to get any hotter than the back of the hand can readily stand, otherwise the bacteria are deformed or destroyed and do not take the stain properly.

The infection may reach the kidney by the blood stream, by lymphatic spread, or by regurgitation up the ureter. The kidney is permanently damaged and its function impaired. Infections of the skin, bone, intestine, throat, teeth, and cervix may act as foci of infection for the urinary tract.

Classification of Urinary Tract Infections.—Cases of urinary tract infection, either pyelonephritis or cystitis, fall into certain natural groups by virtue of the fact that the etiology, pathology, and prognosis differ greatly. Once a case is diagnosed and the group to which it belongs is determined, one can then predict with a high degree of accuracy what the prognosis will be for that particular patient.

SPECIAL FEATURES OF SOME URINARY TRACT INFECTIONS

Pyelonephritis

Acute

In acute pyelonephritis, one or both kidneys may become involved in the inflammatory process. Pyelitis alone almost never occurs, there being an associated pyelonephritis in 99% of cases. This is evidenced by the finding of an acute inflammatory reaction in the interstitial tissue similar to that found elsewhere in the body. The interstitial tissue and tubules are filled with polymorphonuclear leukocytes.

The infection may initially reach the kidney by (1) the blood stream (hematogenous), (2) the lymphatics, and (3) direct ascent up the ureter (urogenous). The latter may occur in neurogenic bladder associated with atonic, neurogenic ureters (reflux up the ureters).

It is probable that most renal infections are hematogenous.

Symptoms.—The patient usually complains of pain or a sense of fullness in the affected kidney. There is a high spiking temperature, and the patient looks toxic. Bladder symptoms of frequency and urgency are usually present when the bladder is involved.

Diagnosis.—A diagnosis is made upon the symptoms described and upon the presence of tenderness of the affected kidney to palpation or tenderness in the costovertebral angle, plus the finding of pus in the urine.

Treatment.—The treatment consists of keeping the patient flat in bed with only one pillow so as to provide better drainage for the kidneys (The kidneys have a normal excursion of approximately $1\frac{1}{2}$ vertebrae. When the patient is in the sitting position they tend to "drop" this normal amount, the ureter bending or folding in an accordion-like manner to take up the slack. Frequently the bend is at the ureteropelvic junction. When the patient is kept flat in bed, the kidney "drops" back into its normal position, and the ureteropelvic junction and ureter are straightened out, thus providing better drainage of the kidney, in spite of the fact that the pelvis of the kidney is at a slightly lower level than the bladder. This position is maintained for only a few days so a week and thus does not increase the tendency to stone formation, described as occurring in "prolonged decubitus.") This is continued throughout each 24-hour period, the patient being allowed to turn on his side to eat but not allowed to sit up. Fluids are given in large amounts. The appropriate chemotherapeutic agent or antibiotic is given. Large, hot linseed poultices are applied to the loin for the relief of pain. Codeine or analgesics may also be given if required. Rarely, a ureteral catheter has to be passed to the renal pelvis and left there for a few days to provide adequate drainage.

Chemotherapy.—There are several chemotherapeutic agents, and every effort is made to select the one effective against the organism involved. Any one drug is continued for a period of not longer than 10 days in order to avoid renal irritation. One would anticipate that by culturing the urine and determining the sensitivity to the various drugs of the organism obtained, it would be relatively easy

to eradicate the infection by using the appropriate drug. However, this frequently has not been the author's experience. For example, one may treat a patient with an *Aerobacter aerogenes* infection sensitive to Chloromycetin with large doses of Chloromycetin for a period of 4-5 days and at the end of that time obtain a culture of the same organism with the same degree of sensitivity. For this reason the author has only a moderate confidence in the sensitivity test. One must also bear in mind whether there still exists obstruction to the urinary flow and the fact that it is not uncommon for the bacterial flora to change completely during treatment, so that one is no longer dealing with *Aerobacter aerogenes* but some totally different organism such as staphylococcus. This in turn may be an indication for a change in therapy.

In the presence of urinary tract obstruction, calculi, or foreign body (urethral catheter, suprapubic tube, or ureteral splint), sterilization of the urinary tract cannot be effected by the usual doses of antibiotics.

The drugs most commonly used are a follows:

1. Mandelamine
2. Mandelic acid and Urotropin
3. Sulfonamides—(sulfathiazole and Gantrisin are the two most effective)
4. Penicillin
5. Streptomycin
6. Antibiotics

A. Three antibiotics all derived from streptomycetes:

- a. Aureomycin
- b. Chloromycetin (chloramphenicol)
- c. Terramycin

B. Antibiotics derived from bacteria

- a. Tyrothricin
- b. Bacitracin
- c. Polymyxin (Aerosporin)

C. Erythromycin (Iliotycin)

D. Tetracycline (synonyms: Achromycin, polycycline), a broad-spectrum antibiotic, effective against both gram-positive and gram-negative organisms

E. Furadantin—(Nitrofurantoin) effective against gram-negative organisms

Summary of effective drugs in order of preference, according to organism involved

1. Any gram negative bacillus—98% of all bacterial infections
 - a Uramand
 - Gantrisin
 - Trisulla
 - b Terramycin or Chloromycetin
 - c Streptomycin
 - d. Combinations of above
2. Any coccal infection (staphylococcus, streptococcus)
 - a. Genticillin
 - b Erythromycin
 - c Tetracycline
 - d Combinations of above
3. Very resistant organisms
 - A Proteus
 - a Chloromycetin
 - b Gantecillin
 - c Furadantin
 - d Tetracycline and streptomycin
 - B Pseudomonas
 - Polymyxin
 - C Any other resistant organism
 - a Furadantin
 - b Combinations of the above groups

For further information see Chapter 3

Complications of Chemotherapy—It must be remembered that certain drugs carry with them the risk of injury when administered in clinical amounts. It is for this reason that antibiotics are administered for only 4-5 days at a time and other drugs for a maximum of 10 days.

Complications of Treatment—

1. Anaphylactic reaction, e.g., penicillin
2. Dermatitis, e.g., penicillin, sulfa drugs
3. Anuria, e.g., sulfa drugs
4. Paralysis and renal damage, e.g., polymyxin
5. Eighth nerve damage, e.g., streptomycin

Sequelae—With the above regime, the acute infection usually quickly subsides. Resolution may become complete, and healing of the inflammatory process with scar tissue replacement occurs. However, one of the most characteristic features of pyelonephritis is its tendency to recur. With each successive attack

the interstitial tissue of the kidney progresses to a chronic inflammatory state, so that eventually a chronic pyelonephritis becomes established.

Chronic

Chronic pyelonephritis is a diffuse infection of the kidney or kidneys which may last for months or years. During this period, acute recurrences of the infection may take place. In the chronic stage the interstitial tissue is filled with lymphocytes, only a few polymorphonuclear leukocytes being present. Colloid

Fig. 439—Microscopic section showing intense interstitial tissue reaction of pyelonephritis

casts are present in the tubules which are lined with atrophic epithelium. Periglomerular fibrosis is also present. With each attempt of the kidney to heal, more scar tissue forms, eventually leading to impairment of renal function. The symptoms are those of recurrent infection and pyemia. The treatment is the same as for an acute infection.

Occasionally one will find on routine pyelography a pyelogram which is typical of chronic pyelonephritis, yet the patient ...

deny ever having had any kidney trouble at any time. The pyelogram will show dilated, blunted calyces, permanently fixed in that position by the surrounding fibrosis.

Pyelonephritic Atrophy

This process of recurrent exacerbations of infection, followed by recession and the laying down of scar tissue, may eventually produce a small contracted kidney referred to as *pyelonephritic atrophy*. Renal function may be so impaired by the large amount of scar tissue present that renal failure ensues. The condition may be unilateral or bilateral.

Necrotizing Renal Papillitis

Necrotizing renal papillitis or *necrotizing pyelonephritis* is a severe type of renal infection that is encountered usually in diabetics. Latent infections in the urinary tract may serve as the foci for the development of more severe lesions at a later date. Pathologically the kidney shows multiple small abscesses in the renal pyramid about the level of two thirds of the way from the papilla to the cortex. As the abscesses coalesce, complete necrosis of the terminal two thirds of the papilla occurs. The process usually involves all the pyramids of the affected kidney. It may be bilateral.

The onset may be fulminating, in which case the patient suddenly becomes desperately ill, or occasionally the process may be slightly less rapid, although equally violent in effect. High spiking temperature, prostration, and rapid pulse are present without signs or symptoms suggestive of urinary tract involvement. The course is rapidly fatal. A correct diagnosis is rarely made before death.

Pyonephrosis

Pyonephrosis refers to an enlarged kidney containing pus. As any inflammatory condition in the kidney progresses over a prolonged period, the delicately defined contour of the calyces is lost. They become club-shaped and gradually increase in size at the expense of the cortex which is thinned out. In a well-developed case the outside of the kidney appears lobulated, the lobulations corresponding

to the thinned-out soft cortex overlying distended calyces. The products of inflammation (pus) accumulate within the kidney. The kidney eventually becomes a mere pyonephrotic sac (pus sac) and is almost if not entirely nonfunctional. If the ureter is open, there is purulent drainage from the sac.

The treatment of pyonephrosis is nephrectomy.

Fig. 440—Pyonephrosis

Group of Infections in Children Under 15 Years of Age

Pyogenic urinary tract infections in children show many features in common. The symptoms are more often referred to the gastrointestinal than to the urinary tract.

1. Response to treatment varies directly as the length of time the symptoms existed before treatment is started.
2. Twenty-five per cent of these patients have recurrent attacks of pyelonephritis 1 to 10 times.
3. Twenty-five per cent have an acute upper respiratory infection immediately preceding the urinary tract infection.

4. Twenty per cent have a congenital lesion in the urinary tract, e.g., aberrant renal vessel, valves in the urethra, etc.

5. Thirty per cent require a major surgical procedure such as a plastic procedure on the renal pelvis, or a nephrectomy, before a cure can be effected.

The Group Complicated by Renal Calculi

1. The infection cannot be cleared up until the calculus is removed. Only 50% succeed in clearing up their infection completely.

2. Thirty per cent develop recurrence of infection.

3. Forty per cent eventually require nephrectomy.

5. Twenty-five per cent are cured during the pregnancy.

6. Ninety per cent are cured within two weeks of emptying the uterus.

Endocrinologic Aspects of Pyelitis of Pregnancy.—The exact cause of dilatation of the ureter during pregnancy is unknown. Some observers believe it is due to the weight of the gravid uterus; others believe that it is due to hormonal factors.

During pregnancy the gonadotropic hormone reaches a maximum excretion in the urine on the 56th day, and thereafter declines rapidly. At the 3rd month of pregnancy the placenta takes over the function of producing and secreting estrin and corpus luteum hor-

Fig. 141.—Relationship between pyelonephritis of pregnancy, hormone excretion in urine, and dilatation of ureter.

The Group of Infections Associated With Pregnancy

1. The incidence of infection diminishes with each successive pregnancy.

2. Two thirds of all the infections occur in the first and second pregnancies.

3. Eighty-five per cent of the patients can be carried to term by conservative treatment.

4. Ninety per cent of these can be delivered of living babies.

mones. This excretion in the urine increases progressively throughout pregnancy.

The incidence of dilatation of the ureter in pregnancy is 52% up to the 5th month of pregnancy, and 92% up to the 9th month. If the incidence of dilatation of the ureter is charted on the graph, it is found that its mean parallels exactly the increased excretion of estrin and corpus luteum hormones during pregnancy.

If one now charts on the graph the incidence of pyelonephritis during pregnancy, it is found that it parallels exactly the incidence of dilatation of the ureter, and both parallel the increased excretion of estrin and corpus luteum hormones in the urine as pregnancy advances

(It has been shown in the Rhesus monkey that if the fetus is removed from the uterus and the placenta left in place, dilatation of the ureter continues. This is what one would expect, since dilatation parallels the excretion of estrin and corpus luteum hormones)

Cystitis Only

1. Treatment consists of chemotherapy and bladder lavage. The drug of choice will depend upon the organism present.
2. Sitz baths are of some value.
3. Stricture of the urethra if present will require dilatation.
4. Prostatitis if present will also require treatment.

Cystitis in the Female Associated With Narrowing of the Urethra

Narrowing of the urethra in middle-aged women is a common finding. There is often an associated cystitis and less frequently a pyelonephritis.

Many of these women are near or have just passed the menopause.

There are four distinct entities which may occur:

1. Narrowing of the urethra with associated cystitis. The patient complains of marked frequency, urgency, and burning on micturition. On catheterization the urethra is found to be tight. There is pus in the urine. Most writers refer to this as stricture of the urethra, which is an unfortunately inaccurate term. What actually happens is that as the menopause is approached, a good many of the elastic fibers in the urethra are replaced by fibrous tissue fibers, so that the urethra loses its elasticity. Here, as elsewhere in the body, fibrous tissue fibers shrink so that the caliber of the urethra becomes relatively narrowed. This in turn produces just enough resistance and obstruction to the flow of urine to cause congestion of the trigone, and it is not long before infection also

develops. These patients respond well to dilatation of the urethra to a Fr. No. 26 sound, bladder lavage, and the proper urinary antiseptic. Stilbestrol may be of help if not contraindicated from a menstrual point of view.

2. In the same category, with the same symptoms except burning but the additional symptom of pain in the bladder, and in any age group (although most do occur near the menopause) is the patient with a markedly reduced bladder capacity, either with or without some narrowing of the urethra. A catheterized or voided specimen of urine will show only a few red blood cells but no pus. However, the basic problem here is not the narrowing of the urethra but the contracted bladder. These patients have an interstitial cystitis in which there is a fibrous adhesion of the mucosa of the bladder to the underlying layers. This was described many years ago by Hunner, who also noted the minute ulcers present. These are infrequently seen.

There have been innumerable treatments devised for this condition, including local excision and fulguration of the area most involved and cortisone therapy. All of these treatments have proved to be remarkably unsatisfactory in curing the symptoms. In the author's experience, the most satisfactory treatment has been the simplest, namely, to stretch the bladder with water under direct cystoscopic vision under general anesthesia. As the bladder is distended from its initial 3 oz. capacity, there suddenly appears a streaking of blood beneath the mucosa, as the adhesions between the mucosa and deeper layers are torn. At this point the dilatation should cease as the bladder capacity will now be between 300-500 ml. Urinary antiseptics should be given prophylactically for 4 days after the dilatation. The patient will now remain asymptomatic for a period of 3 months to 1 year, at the end of which time the dilatation should be repeated.

3. The third group of women have either the interstitial cystitis or the cystitis with the narrowing of the urethra as described, plus a cervicitis or vaginitis. Many of the vaginal infections are due to *Trichomonas* or *Monilia*. Again, unless the cervicitis and vaginitis are eliminated, the urinary symptoms will not disappear. One should bear in mind the possi-

bility of the husband being the cause of re-infection.

Care is taken to exclude an unsuspected carcinoma of the cervix. Cervical smears stained by the Papanicolaou technique are of great assistance.

4. A few of these patients, particularly in the older age group, have, in addition to a tightness of the urethra, the presence of a thickening of the bladder neck, with definitely hypertrophied prostatic prongs causing a mechanical obstruction. A resection of the bladder neck is required to remove the obstructing tissue.

Infections Associated With Overgrowth of Prostate

In men in whom the prostate hypertrophies, there develops an obstruction at the bladder neck. As the obstruction increases, the bladder fails to empty completely, so that a residual urine remains. As this urine is more or less stagnant, it is an ideal breeding ground for bacteria. Thus cystitis in a patient with an enlarged prostate is not an uncommon finding. Furthermore, calculi may and often do form in this infected, stagnant urine; also the bladder becomes infected immediately when it is opened and a tube inserted. Following a prostatectomy every patient has a cystitis. Its duration will depend upon the intensity of the chemotherapeutic measures directed at elimination of the infecting organisms. If the infection is not cleared up postoperatively, fibrosis of the bladder neck may occur. As a rule it requires 2-3 months of postoperative care to eradicate the infection. Treatment consists of bladder irrigations once a week and the appropriate chemotherapeutic or antibiotic agent according to the bacteria present.

Infections Occurring in Fractured Pelvis, Ruptured Bladder, and Cord Bladder

Each case is treated as an individual problem according to the principles outlined above.

Perinephric Abscess

Perinephric abscess is an abscess that forms around the kidney and is almost always due to rupture of a cortical abscess. The organism most commonly found in the pus is the staphy-

lococcus, the next most common being *B. coli*. It frequently follows staphylococcal abscesses on the skin or inside the nose.

Symptoms.—The symptoms most commonly found are pain, a sense of fullness in the lumbar region, chills, fever, and prostration.

Physical Signs.—As the abscess increases in size it will spread downward along the psoas muscle and also posteriorly in the loin, causing a bulging with recognizable deformity. The bulging area is tender to palpation and may be fluctuant.

X-ray Signs.—The x-ray signs of a perinephric abscess are usually diagnostic:

1. There is curvature of the lumbar spine with the convexity away from the abscess.

2. Obliteration of the psoas muscle shadow occurs on the affected side.

3. The ribs, or lumbar transverse processes, or both may be obscured.

4. There may be displacement of the colon or fixation of the diaphragm on the same side if the abscess has existed for some time.

5. The kidney may be shown by intravenous pyelograms to be fixed and to lack its normal mobility.

6. There may be anterior displacement of the kidney.

7. In some cases of perinephric abscess, there is lateral displacement of the kidney with medial displacement of the ureter.

8. Pyelograms may show rotation of one calyx, indicating the presence of an abscess.

Diagnosis.—This is made on the symptoms, physical signs, and x-ray findings.

Prognosis.—The abscess will continue to increase in size until such time as it is incised and drained. If it goes unrecognized, rupture into the pleural cavity or into the peritoneal cavity occurs, either of which may be fatal.

Treatment.—If the abscess is recognized early, it may disappear completely with intensive penicillin therapy. If, however, a recognizable mass is present in the loin, incision and drainage must be carried out. Two or three Penrose drains with wicks are inserted to maintain drainage. Penicillin therapy is given. When the acute condition subsides, the functional status of the kidney is determined and a decision made as to whether or not nephrectomy will be required.

If one now charts on the graph the incidence of pyelonephritis during pregnancy, it is found that it parallels exactly the incidence of dilatation of the ureter, and both parallel the increased excretion of estrin and corpus luteum hormones in the urine as pregnancy advances.

(It has been shown in the Rhesus monkey that if the fetus is removed from the uterus and the placenta left in place, dilatation of the ureter continues. This is what one would expect, since dilatation parallels the excretion of estrin and corpus luteum hormones.)

Cystitis Only

1. Treatment consists of chemotherapy and bladder lavage. The drug of choice will depend upon the organism present.
2. Sitz baths are of some value.
3. Stricture of the urethra if present will require dilatation.
4. Prostatitis if present will also require treatment.

Cystitis in the Female Associated With Narrowing of the Urethra

Narrowing of the urethra in middle-aged women is a common finding. There is often an associated cystitis and less frequently a pyelonephritis.

Many of these women are near or have just passed the menopause.

There are four distinct entities which may occur:

1. Narrowing of the urethra with associated cystitis. The patient complains of marked frequency, urgency, and burning on micturition. On catheterization the urethra is found to be tight. There is pus in the urine. Most writers refer to this as stricture of the urethra, which is an unfortunately inaccurate term. What actually happens is that as the menopause is approached, a good many of the elastic fibers in the urethra are replaced by fibrous tissue fibers, so that the urethra loses its elasticity. Here, as elsewhere in the body, fibrous tissue fibers shrink so that the caliber of the urethra becomes relatively narrowed. This in turn produces just enough resistance and obstruction to the flow of urine to cause congestion of the trigone, and it is not long before infection also

develops. These patients respond well to dilatation of the urethra to a Fr. No. 26 sound, bladder lavage, and the proper urinary antiseptic. Stilbestrol may be of help if not contraindicated from a menstrual point of view.

2. In the same category, with the same symptoms except burning but the additional symptom of pain in the bladder, and in any age group (although most do occur near the menopause) is the patient with a markedly reduced bladder capacity, either with or without some narrowing of the urethra. A catheterized or voided specimen of urine will show only a few red blood cells but no pus. However, the basic problem here is not the narrowing of the urethra but the contracted bladder. The patient will now remain asymptomatic for a period of 3 months to 1 year, at the end of which time the dilatation should be repeated.

3. The third group of women have either the interstitial cystitis or the cystitis with the narrowing of the urethra as described, plus a cervicitis or vaginitis. Many of the vaginal infections are due to *Trichomonas* or *Monilia*. Again, unless the cervicitis and vaginitis are eliminated, the urinary symptoms will not disappear. One should bear in mind the possi-

hility of the husband being the cause of re-infection.

Care is taken to exclude an unsuspected carcinoma of the cervix. Cervical smears stained by the Papanicolaou technique are of great assistance.

4 A few of these patients, particularly in the older age group, have, in addition to a tightness of the urethra, the presence of a thickening of the bladder neck, with definitely hypertrophied prongs causing a mechanical obstruction. A resection of the bladder neck is required to remove the obstructing tissue.

Infections Associated With Overgrowth of Prostate

In men in whom the prostate hypertrophies, there develops an obstruction at the bladder neck. As the obstruction increases, the bladder fails to empty completely, so that a residual urine remains. As this urine is more or less stagnant, it is an ideal breeding ground for bacteria. Thus cystitis in a patient with an enlarged prostate is not an uncommon finding. Furthermore, calculi may and often do form in this infected, stagnant urine; also the bladder becomes infected immediately when it is opened and a tube inserted. Following a prostatectomy every patient has a cystitis. Its duration will depend upon the intensity of the chemotherapeutic measures directed at elimination of the infecting organisms. If the infection is not cleared up postoperatively, fibrosis of the bladder neck may occur. As a rule it requires 2-3 months of postoperative care to eradicate the infection. Treatment consists of bladder irrigations once a week and the appropriate chemotherapeutic or antibiotic agent according to the bacteria present.

Infections Occurring in Fractured Pelvis, Ruptured Bladder, and Cord Bladder

Each case is treated as an individual problem according to the principles outlined above.

Perinephric Abscess

Perinephric abscess is an abscess that forms around the kidney and is almost always due to rupture of a cortical abscess. The organism most commonly found in the pus is the staphy-

lococcus, the next most common being *B. coli*. It frequently follows staphylococcal abscesses on the skin or inside the nose.

Symptoms.—The symptoms most commonly found are pain, a sense of fullness in the lumbar region, chills, fever, and prostration.

Physical Signs.—As the abscess increases in size it will spread downward along the psoas muscle and also posteriorly in the loin, causing a bulging with recognizable deformity. The bulging area is tender to palpation and may be fluctuant.

X-ray Signs.—The x-ray signs of a perinephric abscess are usually diagnostic:

- 1 There is curvature of the lumbar spine with the convexity away from the abscess.
- 2 Obliteration of the psoas muscle shadow occurs on the affected side.
- 3 The ribs, or lumbar transverse processes, or both may be obscured.
- 4 There may be displacement of the colon or fixation of the diaphragm on the same side if the abscess has existed for some time.
- 5 The kidney may be shown by intravenous pyelograms to be fixed and to lack its normal mobility.
- 6 There may be anterior displacement of the kidney.
- 7 In some cases of perinephric abscess, there is lateral displacement of the kidney with medial displacement of the ureter.
- 8 Pyelograms may show rotation of one calyx, indicating the presence of an abscess.

Diagnosis.—This is made on the symptoms, physical signs, and x-ray findings.

Prognosis.—The abscess will continue to increase in size until such time as it is incised and drained. If it goes unrecognized, rupture into the pleural cavity or into the peritoneal cavity occurs, either of which may be fatal.

Treatment.—If the abscess is recognized early, it may disappear completely with intensive penicillin therapy. If, however, a recognizable mass is present in the loin, incision and drainage must be carried out. Two or three Penrose drains with wicks are inserted to maintain drainage. Penicillin therapy is given. When the acute condition subsides, the functional status of the kidney is determined and a decision made as to whether or not nephrectomy will be required.

GENTOURINARY SYSTEM

Renal Carbuncle

A renal carbuncle may start by the fusion of several smaller cortical abscesses or by the progressive enlargement of one abscess. As it increases in size it becomes demarcated from the surrounding healthy kidney tissue, and its core becomes necrotic. The carbuncle may involve one whole pole of the kidney or even the entire kidney, together with perinephric fat.

The symptoms are those of an acute infection, with a high temperature and tenderness to palpation in the kidney region.

The carbuncle may rupture into the renal pelvis and empty itself spontaneously via the ureter, or it may rupture into the perinephric space, producing a perinephric abscess.

An acute fulminating infection is treated with intensive penicillin therapy. Nephrectomy

may be required during the acute stage to save the patient's life but, if possible, is deferred. When the acute condition has subsided, nephrectomy will be required if the suppurative process is found to be extensive.

Abacterial Pyuria

Abacterial pyuria is an infection of the urinary tract in which numerous pus cells are found but in which one fails to recover organisms either on direct smear or on culture. These infections respond very promptly to the intravenous administration of arsenicals (neoarsphenamine, Mapharsen). This has led to the belief that the infection is caused by an unidentified spirochete. The prompt response to arsenical therapy has led others to believe that the infection is caused by Leishman-Donovan bodies.

URINARY CALCULI

Theories of Origin

Theories concerning the etiology of urinary calculi are numerous and conflicting. There is no one constant series of events found in all cases presenting calculus formation.

The etiologic factors may be classified as follows:

Personal Factors.—

1. Deficiency of vitamin A
2. Dehydration
3. Prolonged decubitus
4. Bacterial infections
5. Congenital anomalies causing obstruction
6. Hyperparathyroidism

Until recently, deficiency in vitamin A was considered to be of great importance in the formation of urinary calculi. Subsequent studies of patients with calculi, however, revealed that only a very few were actually deficient in vitamin A. This theory has therefore been discarded.

Dehydration appears to be of some significance in the formation of urinary calculi. More cases of patients suffering from colic are seen in the hot summer months than during the winter. In World War II the incidence of calculi in the troops involved in

desert warfare was unusually high. This was thought to be due to dehydration.

It is generally accepted that prolonged decubitus tends to increase the incidence of urinary calculi. When a patient is immobilized for a prolonged period, there is increased mobilization of calcium which is derived from the whole skeleton but especially from the long bones.

There is an increased tendency to stone formation in patients so immobilized. This is considered due in part to increased mobilization of calcium and partly to the effects of stagnation caused by the prolonged supine position. It is interesting to note that, in this position, the renal pelvis is at the lowest level in the urinary tract in the horizontal plane. This means that urine has to pass upward to a higher level to reach the ureter and flow into the bladder. There is thus a natural tendency to stagnation in the renal pelvis when a patient is kept in the decubitus position for any length of time. This particular factor can be overcome by the use of an oscillating bed or by placing a board frame with a central fulcrum under the standard mattress, so as to permit the patient to alter his position.

Bacterial infection is the main causative factor in many urinary calculi. This is confirmed by the fact that infected urine is obtained by catheterization from the kidney involved and that certain types of calculi, e.g., calcium phosphate, form only in infected urine. The organism *B. proteus* is the greatest offender and the most difficult to eradicate. Staphylococci are the next commonest organisms which predispose to stone formation. Usually it is impossible to eradicate infection in a kidney in which a calculus is present until the calculus has been removed. Conversely, unless the infection is eradicated, calculi will almost certainly reform. The incidence of recurrence of renal calculi varies from 10-40% in different clinics.

Patients with *obstruction*, e.g., aberrant renal vessels at the ureteropelvic junction, stricture, etc., are particularly prone to develop calculi. This is due to the effect of prolonged impairment to drainage from the kidney, resultant stagnation of urine, and increased susceptibility to infection.

Approximately 5% of recurrent urinary calculi are due to *hyperparathyroidism*. Hyperparathyroid disease is discussed in Chapter 13.

Race and Geographic Distribution.—The white and yellow races are relatively susceptible to the formation of urinary calculi. The Negro race is relatively immune.

There appear to be definite stone-bearing areas in the world. Urinary calculi are much more common in India and China than in other countries. Just what effect soil and climate have on the formation of calculi is not known.

Theories of Physical Factors Associated With Stone Formation.—Considerable speculation regarding the origin of urinary calculi was based on the results of chemical analysis. In turn, a theory was developed in which the causes were attributed to various physical factors.

1. *The presence of stone-forming substances in the urine.* Every specimen of urine contains stone-forming elements, e.g., uric acid and calcium oxalate. The solubility of these substances depends upon the following.

a. The pH of the urine. At pH 5 pure uric acid is present to the point of saturation. At

pH 7, the urine is supersaturated with calcium oxalate.

b. The presence of other electrolytes in the urine. The solubility of a sparingly soluble electrolyte is increased by the presence of other more soluble electrolytes, e.g., the solubility of uric acid is increased by the presence of sodium phosphate.

c. The presence of certain nonelectrolytes. The solubility of a salt in a solution may be greatly increased by the presence of another salt in the same solution, e.g., the solubility of calcium oxalate in water is doubled by adding urea.

2. *The protective action of urinary colloids.* The urinary colloids consist of mucin, nucleic acid, chondroitin sulfuric acid, and a complex nitrogen-containing carbohydrate. They are suspended in solution, and their precipitation may lead to the formation of the nucleus of a future calculus. The nucleus of the developing calculus will continue to grow provided (a) it is retained within the urinary tract and (b) the urine continues to supply an excess of stone-forming salts.

This theory advocated by Swift, Joly, and others has considerable appeal. It tends to explain the physical factors concerned but is totally unable to explain many of the other known factors in calculus formation. It is perhaps much closer to the truth to say that the exact cause of calculus formation is not known in all cases, although many of the contributing factors have been recognized.

If a catheter is passed up each ureter to the renal pelvis and specimens of urine are obtained from patients with renal calculi, in whom hypercalcaemia is present, urine from the kidney containing the calculi is found to have an excess of calcium, whereas urine from the other kidney is found to contain a normal amount of calcium. This suggests that in the normal kidney there is some mechanism which holds back calcium and acts as a filter. If a calculus is present, this mechanism may become damaged, allowing an excess of calcium to escape in the urine. Since the normal exchange of calcium and phosphate ions is across the tubular membrane, it is possible that the disease may begin there.

Lymph Channel Origin of Calculi.—Carr has recently enunciated an entirely new theory of stone formation. He has shown that normal kidneys contain radiopaque bodies measuring 0.2 mm. in diameter. Several concretions may coalesce and lie in a line. He has shown that these concretions occur just outside the fornices of the calyces in line with but outside both the arteries and veins, i.e., in the lymphatic channels. As the concretion increases in size, it grows toward the pelvis, finally ulcerating through into it to give a true renal calculus. The so-called "plaques of Randall" he believes are in fact multiple concretions aggregated together in the lymph channels

ward, forward, and medially along the course of the ureter. It may also radiate into the testicle or the medial aspect of the thigh on the affected side.

There are three points of narrowing along the course of the ureter. A stone is likely to become lodged at these points of constriction: (1) the ureteropelvic junction, (2) the point at which the ureter crosses the iliac vessels, and (3) the entrance of the ureter into the bladder.

A sharp or irregular stone may become embedded in the mucous membrane of the ureter anywhere along its course.

TABLE 34
CLASSIFICATION OF CALCULI

	URINE		CHEMICAL COMPOSITION	MINERALOGIC NAME
	ACID	ALKALINE		
A Organic				
1 Uric acid calculi				
a Uric acid	+			
b Urates		+		
c Xanthine	+			
2 Cystine calculi	+			
B Inorganic				
1 Primary calcium calculi				
a Calcium oxalate monohydrate	+		$\text{CaCO}_3 \cdot \text{H}_2\text{O}$	Whewellite
b Calcium oxalate dihydrate	+		$\text{CaC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$	Weddellite
c Calcium carbonatophosphate		Neutral to alkaline	$\text{Ca}_3(\text{PO}_4)_2 \cdot 2\text{CaCO}_3$	Carbonatapatite
d Calcium phosphate		Neutral to alkaline	$\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$	Brushite
2 Magnesium-containing calculi (May also contain carbonate and phosphate and magnesium ammonium phosphate)		+	$\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$	Struvite

Pathology

Most calculi are due to obstruction, bacterial infection, or ulceration, either alone or in combination. Some form as plaques on the renal papillae without evidence of any of the above factors.

Symptoms of Renal and Ureteral Calculi

A calculus in the kidney may be large and silent. A stone weighing 432 Gm. (1 pound) was removed from a patient who had no symptoms referable to the kidney. Small calculi produce attacks of acute renal or ureteral colic as they pass down the ureter. The pain begins in the lumbar region posteriorly, is sudden in onset, colicky in nature, and passes down-

Diagnosis of Renal or Ureteral Calculus

1 History of acute pain in the loin, sudden in onset, colicky in nature, radiating downward, forward, and medially into the bladder, testicle, or medial aspect of the thigh on the affected side. The pain may be so severe as to cause collapse.

2 On physical examination, there is splinting of the muscles on the affected side and tenderness to palpation.

3. The urine usually shows scattered red blood cells. It should be remembered that a voided specimen of urine is desirable in these cases, as the passage of a catheter may in itself be sufficiently traumatic to produce scattered red blood cells in the urine.

URINARY CALCULI

Fig. 442—Plain film of kidney ureter bladder area showing fairly large calculus in left mid ureter opposite transverse process of 3rd lumbar vertebra

Fig. 443—X ray of abdomen showing large stag horn calculus in the left kidney.

Fig. 444—The three points of narrowing of the ureter

4. A plain x-ray plate of the kidney, ureter, and bladder area will reveal the site, size, and number of calculi present if they are radiopaque. Approximately 5% are nonopaque.

5. Cystoscopic examination and ureteral catheterization are performed. X-rays taken in the anteroposterior and oblique diameters with the catheter in situ will show conclusively whether or not the calculus is in the ureter. If a calculus is present in the ureter, the opacity seen on x-ray will remain in contact with the catheter in both the anteroposterior and oblique projections. However, if the opacity is seen to lie one-half inch or so away from the catheter in either projection it can be said with certainty that the opacity is not due to a calculus in the ureter, regardless of the other symptoms present. In the latter case the shadow may be due to a calcified gland or phlebolith.

Treatment

1. Emergency relief of the colic by giving morphine 15 mg and atropine 0.4 mg.
2. Prevention—try to correct the underlying condition if possible.
3. Surgical—the particular type of surgical procedure to be employed depends upon the conditions present and may be any of the following.

Operations on the Kidney.—

1. Remove the calculi—x-ray at the time of operation to make certain all the calculi are removed.
 - a. Pyelotomy—i.e., open the pelvis of the kidney and remove the calculus.
 - b. Nephrolithotomy—i.e., approach the stone through the substance of the kidney.
2. Remove obstructions at the time of the pyelotomy or nephrolithotomy, e.g., if uretero-

pelvic obstruction is present do a plastic procedure at the site of obstruction.

3. Nephrectomy—if the disease is advanced.

Operations on the Ureter.—

1. The ureteral orifice and ureter may be dilated with bougies.
2. Or be cut on the affected side with cystoscopic scissors or a cautery wire.
3. If the calculus is low in the ureter and not too large, a stone basket may be passed and the calculus removed. Serious trauma to the ureter may be caused by rough handling of a stone basket. An edematous seminecrotic ureter may be perforated, the infection thereby being spread outside the ureter into the retroperitoneal plane with the production of a perinephric abscess.
4. The ureter may be incised over the calculus and the calculus removed.

Dietary.—

1. Vitamin A is said to be of some value, but this is doubtful.
2. Cystine stones can be prevented and perhaps even reabsorbed by (a) reducing proteins in the food to a minimum or (b) by giving alkalis to keep the urine constantly alkaline.
3. Attempts have been made to dissolve calcium and phosphate calculi by using buffered citric acid solutions as irrigations (solutions G and M). In our experience these have not been successful.
4. Some authors believe that the presence of citric acid in the urine increases the solubility of the calcium salts. Estrogenic hormone is given to increase the excretion of citric acid in the urine, thereby increasing the solubility of calcium. Aluminum hydroxide gel is given at the same time, to increase the elimination of phosphates by the bowel and diminish the amount available to the kidney.

GENITOURINARY TUBERCULOSIS

Genitourinary tuberculosis may affect the kidney, prostate, seminal vesicles, epididymis, fallopian tubes, or bladder. It may be limited to any one of these organs, with the exception of the bladder. Its most characteristic feature is its marked tendency to spread and this plays the predominant role in deciding the treatment.

It must also be borne in mind that tuberculosis is a generalized infection and that urogenital tuberculosis is only a local manifestation. Such infection is usually secondary to a primary focus in the lungs, intestinal tract, tonsils, or bones. The primary focus can be found in approximately 80% of cases. In

searching for a primary focus, one should also bear in mind that an early pulmonary lesion may not be detectable by radiologic means until 6 months after its onset.

Age.—Genitourinary tuberculosis is rare under the age of 10 years and, if present at this age, is almost always of the acute fulminating type. Seventy per cent of cases occur between 20-40 years of age.

Incidence.—The incidence of genitourinary tuberculosis is approximately 1.2% in routine autopsies, 5% in autopsies on tuberculous patients dying of other diseases, and 10% in patients dying of tuberculosis.

The incidence of the bovine type in genitourinary tuberculosis is exceedingly low.

In cases of genitourinary tuberculosis, the prostate, seminal vesicles, or epididymis is involved in 65-75% of the cases. Primary tuberculosis of the prostate gland alone is rare.

Renal Tuberculosis

Renal tuberculosis is the result of the introduction, implantation, and germination of the tubercle bacillus in the renal bed. The extent of the lesion depends upon the virulence of the bacillus and the resistance of the host.

There are three main types of lesion in the kidney:

1. **Acute miliary**—fulminating bilateral renal lesions, which are part of a generalized miliary tuberculosis.
2. **Chronic form**, in which there is abscess formation with caseation, referred to as surgical renal tuberculosis.
3. **Toxic tuberculous nephritis**, which is a renal manifestation of grave systemic tuberculosis, without definite involvement of the urinary organs; exceedingly rare.

Etiology.—Renal tuberculosis is always hematogenous in origin, the primary focus being in the lungs, tonsils, intestinal tract, or bone. The infection in the primary area progresses until the tubercle bacilli finally invade the blood stream. If the invasion of the blood stream is massive, general miliary tuberculosis results. If the organisms enter the blood stream in showers, the phagocytic cells of the body may overcome them. If the patient's general and local resistance is sufficient, the secondary

lesion in the kidney may heal; otherwise it progresses with eventual destruction of the kidney. Renal and other secondary lesions in the prostate, seminal vesicles, and epididymes may all originate from the same primary focus in the lungs, tonsils, or intestinal tract. Conversely, the renal lesion may be derived from infection in the prostate, seminal vesicles, or epididymis, and carried to the kidney by the blood stream. It is the consensus that renal tuberculosis is blood borne and that tuberculous infection ascending the ureter or the lymphatics does not occur.

Pathogenesis.—It is now generally accepted that a bacillus-laden embolus is carried into the kidney by the blood stream and lodges in a capillary tuft. The glomerular focus may be walled off or a few bacilli may reach the capsular space and multiply while being washed slowly along the proximal convoluted tubule until they reach a favorable soil for growth in the medullary loop. The bacilli may, however, reach the medulla by way of the fine efferent glomerular capillaries. The final method of infection is by spread of cortical lesions to the medulla by the lymphatics.

Opinions differ as to whether the initial lesions in the kidney are predominantly cortical or medullary. Medlar, who did 100,000 sections on 44 separate tuberculous kidneys, found 367 definite tuberculous lesions of which 75% were in the cortex, 11% were in the medulla, and 14% were corticomedullary.

The initial glomerular lesion may heal, continue to grow slowly, or rarely develop into the main lesion. The medullary lesion usually grows relatively fast. Such a tubercle will spread and finally open into a renal tubule or papilla, discharging its contents into the renal pelvis. If the medullary lesion is near a calyx, it will give rise to early symptoms. If it is deep in the parenchyma there may be extensive damage before there are any clinical signs. Healing of this type of lesion is rare.

The Question of Initial Bilateral Involvement.—Of the many disputed points concerning renal tuberculosis none has been more discussed than the question as to whether, at the outset, one or both kidneys are involved. Many investigators believe the implantation is bilateral but that the disease develops in only one kidney.

The Excretion of Tubercle Bacilli in the Urine.—The presence of tubercle bacilli in the urine represents a break in the integrity of the renal mucous membrane and is regarded as the essential evidence of disease within the renal parenchyma.

Secondary infection occurs frequently. In urine obtained from a tuberculous patient organisms other than tubercle bacilli, e.g., *E. coli*, staphylococci, are found in 20% of cases. It is therefore important to exclude tuberculosis in all cases of persistent urinary infection.

Symptoms of Renal Tuberculosis.—

1. Frequency, day and night, is present in 75% of the cases.

2. Painful urination is often present.

3. Hematuria, microscopic or macroscopic occurs in 50% of the cases

a. Terminal bleeding common

b. Smoky urine

c. Microscopic red blood cells

d. Gross hematuria rare

4. Dribbling is usually a sign of pronounced vesical involvement.

Diagnosis.—

1. History.

2. The recovery of tubercle bacilli from the urine is the essential evidence of active disease within the renal parenchyma (a) by direct smear, (b) positive urine cultures, (c) guinea pig inoculation of urine from each kidney

3. Retrograde pyelograms demonstrating alterations in the renal architecture

Treatment of Renal Tuberculosis.—The incidence of bilateral renal tuberculosis will vary, depending upon the promptness with which observation and urologic investigation are undertaken. It is bilateral in 20-45% of cases. It is of the greatest value to know the patient's ability to fight his disease, the pathologic type of the disease, and the prognosis insofar as the pulmonary lesion is concerned.

The use of streptomycin with para-aminosalicylic acid has considerably altered the technique of treating renal tuberculosis. The recent addition of isoniazid has likewise improved the treatment. Isoniazid is 600 times more effective than para-aminosalicylic acid alone and is as bacteriostatic as streptomycin against the tubercle bacillus. However, like streptomycin, the tubercle bacillus develops a resistance to it in approximately 2-8 weeks.

Therefore the current use of these three drugs, each of which has a different mode of action on the tubercle bacillus, is as follows and for a period of 2 years:

a. Isoniazid—3 mg./kilo body weight in 3 divided doses daily

b. Streptomycin hydrochloride (preferred to dehydrochloride) 1 Gm. 3 times weekly

c. Para-aminosalicylic acid 5 Gm. daily

With this treatment there is clinical improvement in some and marked improvement in other cases. In bilateral renal tuberculosis it is usually advisable to remove the more severely infected kidney, giving the triad of

Fig. 445—Pyelogram showing deformity caused by renal tuberculosis

chemotherapy concurrently. The chemotherapy is started one week preoperatively and continued for 2 years postoperatively. This frequently results in healing of the lesion in the less involved kidney.

Tuberculous epididymitis responds very slowly, if at all, to streptomycin therapy. This lack of response may be due to failure to obtain an adequate drug concentration in the tissue. Tuberculous scrotal sinuses respond promptly to streptomycin therapy.

FIG 416—Gross specimen of renal tuberculosis

Streptomycin is not used in patients with a small contracted tuberculous bladder as this will achieve only slight improvement of the clinical symptoms but will not alter the overall picture.

Institution of operative measures at the proper time for chronic renal tuberculosis rarely causes a flare-up of the associated pulmonary disease. Surgery should be delayed whenever possible until the pulmonary lesion has become quiescent.

In cases of renal tuberculosis, the normal-appearing ureter will show microscopic tuber-

culous lesions in 30% of cases. It is for this reason that many surgeons recommend nephroureterectomy for renal tuberculosis, even though the ureter appears normal at the time of operation.

Summary of Treatment (Table 35).—All cases of genitourinary tuberculosis, especially after surgery:

1. Complete bed rest
2. Sanatorium treatment, or the equivalent at home for a period of 3 months

The severity of the symptoms should be a strong factor in determining treatment. One

TABLE 35
TREATMENT OF RENAL TUBERCULOSIS

UNILATERAL	BILATERAL
Medical treatment—Isoniazid, streptomycin and para-aminosalicylic acid	Triad of chemotherapy for 2 years
Surgical treatment—Nephrectomy or nephroureterectomy if the kidney is completely destroyed, to be preceded and followed by isoniazid, streptomycin and para-aminosalicylic acid	<ol style="list-style-type: none"> a Isoniazid b Streptomycin c Para-aminosalicylic acid
	1 Remove the more diseased kidney, if healing has not occurred after 1 year of triple therapy, plus the triad of chemotherapy
	2 Bilateral cutaneous or intestinal ureteral transplant in advanced bilateral disease—to be preceded and followed for 1 year by triad of chemotherapy

does not like to do a bilateral cutaneous transplant because its care is difficult for the patient.

Tuberculosis of the Bladder

Tuberculosis of the bladder is secondary to tuberculosis of the kidneys or seminal tract in the male. In the female it may be secondary to tuberculosis of the pelvic organs. In the majority of cases the primary focus is in the kidney. The ureteral orifice on the affected side is usually involved.

Involvement of the bladder, secondary to a tuberculous focus in the prostate or urethra, occurs by direct mucosal extension. In such cases the trigone is practically always the point of first attack. In most cases, however, the bladder involvement is due to the planting of tubercle bacilli from infected urine directly on the vesical mucosa, the resistance of which has been lowered by the continuous irritation of infected urine. This leads to inflammation, edema, ulceration, and finally fibrosis of the bladder wall. The bladder becomes contracted and its capacity greatly reduced.

Symptoms.—

1. Intense frequency
2. Painful urination, the pain occurring at the end of micturition

3. Slight, intermittent hematuria

Diagnosis.—

1. Appearance of the bladder at cystoscopy, small tuberculous ulcers
2. The recovery of tubercle bacilli from the urine

Prognosis.—If the source of the vesical infection is removed (usually a tuberculous kidney), the bladder condition often heals rapidly. If, however, the original source of the disease is not eliminated, it is practically impossible to cure, or even materially relieve, a tuberculous cystitis. When treatment is completed, sanatorium care should be instituted.

Tuberculosis of the Prostate

Tuberculosis of the prostate alone is very rare. It is usually part of a progressive infection that is extending throughout the genital or urogenital system, being present in about 70% of cases of urogenital tuberculosis. In

most instances tuberculosis of the prostate occurs by direct extension from the seminal vesicles. Urogenital tuberculosis tends to spread from one portion of the urinary tract to another.

Symptoms.—

1. None at all
2. Frequency, dysuria, hematuria, pyuria

Diagnosis.—

1. Rectal examination—the prostate feels firm, irregular, and nodular
2. Examination of the prostatic fluid for tubercle bacilli
3. A plain x-ray of the pelvis to show, if possible, areas of calcification in the prostate

Treatment.—

1. Total perineal prostatectomy gives poor results. Chronic sinuses may result.
2. Sanatorium rest or the equivalent thereof often gives relief of symptoms, although the course of the disease is essentially unaltered.
3. Antibiotics are useful.

Tuberculosis of the Epididymis and Testicle

Autopsy records show that tuberculous lesions may be limited to the epididymes, seminal vesicles, or prostate but that such limitation is rare. Clinically the majority of cases exhibit multiple lesions. The infection in the epididymis usually begins in the globus minor and gradually extends throughout the epididymis and into the vas. The tuberculous process in the epididymis may assume such extensive proportions that the testicle becomes a small compressed organ.

The disease sometimes appears to be bilateral from the onset. When tuberculosis infects only one epididymis the opposite epididymis is likely to become infected sooner or later. For this reason it is advisable to do a vasectomy on the unaffected side.

Tuberculosis of the testicle is very rare. It is usually secondary to tuberculosis of the epididymis. The entire testicle may become a hard mass by gradual extension of the disease. The scrotum becomes adherent to the mass; the process finally ulcerates through the skin to form a chronic fistula discharging caseous material. The function of the affected organ

is destroyed and, should the process become bilateral, complete sterility is inevitable.

Sinuses on the posterior surface of the scrotum are from the epididymis. Those on the anterior surface are from the testicle. A persistent scrotal sinus of months' or even years' duration is frequently the reason the patient seeks medical advice.

Diagnosis.—

1 History of trauma is present in many cases, frequently it is this that draws the patient's attention to the fact that there is a swelling present in the scrotum

2 Loss of weight and general malaise are usually present

3 Bladder symptoms may be present

4 Fever is rare.

5 Pain and tenderness in the epididymis are mild and intermittent

6 There is history of exacerbations and remissions of the swelling

7. On palpation the epididymis is found to be swollen, nodular, and irregular in contour.

8 A persistent draining sinus may be present.

Differential Diagnosis—

1. Tuberculous epididymitis

2. Inflammation due to other causes

Prognosis.—The high morbidity of genital tuberculosis, even when properly treated, is not generally appreciated. The disease is progressive and fairly rapid in its evolution. Prior to the use of antibiotics the ultimate mortality varied from 27-60%. The patient must be examined yearly for 10 years

Treatment.—

1. Epididymectomy—with transplantation of the vas to the skin of the groin

2. Six months' sanatorium treatment or the equivalent at home

3. Antibiotics

BLADDER

Anatomy.—The bladder is a reservoir for urine. It is a musculomembranous sac situated in the bony pelvis behind the pubis and in front of the rectum in the male. In the female it is separated from the rectum by the cervix uteri and the vagina.

When empty, the bladder is pyriform in shape, with the apex below. The ureter of each side is connected to each of the upper angles of the triangle, and the urethra is connected below. The urachus (obliterated allantoic duct) connects the bladder to the umbilicus. The superior or upper surface of the bladder is covered with peritoneum. The normal bladder capacity is approximately 500 ml of fluid.

The interior of the bladder is lined with folds and shows on the floor the vesical trigone, a pale-colored triangular space, marked at its upper and outer angles by the entry of the ureter on each side (ureteral orifice) and extending below to the opening of the urethra. The interureteric ridge runs transversely between the two ureteral orifices.

Blood Supply.—The arteries of the bladder are the superior vesical, middle vesical, and

inferior vesical in the male, with additional branches from the uterine and vaginal arteries in the female. These are all derived from the anterior trunk of the internal iliac artery.

The veins form a plexus around the neck, sides, and base of the bladder and terminate in the internal iliac veins.

The lymphatics terminate in the internal iliac nodes.

Developmental Embryology.—The rudimentary alimentary canal ends below in a blind pouch known as the cloaca, which has a prolongation known as the allantoic diverticulum which later becomes the urachus. The mesonephric duct which later becomes the vas deferens opens into the anterior part of the cloaca. The ureters develop as an outgrowth of this duct. In time this common duct is absorbed into the wall of the bladder and prostatic urethra, with the result that the vas and the ureter eventually develop separate openings. A urorectal septum then forms which divides the cloaca into an anterior, or urogenital, part and a posterior, or intestinal, part.

Extrophy of the bladder is a developmental anomaly in which the anterior surface of the

bladder fails to close. There is a corresponding defect in the abdominal wall, so that the floor of the bladder presents on the anterior abdominal wall. The ureteral orifices usually protrude.

Nerve Supply.—The nerve supply of the bladder, ureter, and urethra is of three sources sympathetic, parasympathetic, and somatic. The sympathetic fibers which innervate the bladder are derived from T11-12 and L1-2, and come together in a strand called the *presacral nerve*. Lateral roots connect this to the 1st and 2nd lumbar prevertebral sympathetic ganglia. A middle root from the preaortic nervous plexus

traction. The middle portion supplies the urethra and genitalia, the distal portion innervates the bowel.

The *somatic* fibers from S 3-4 pass in the *pudendal nerves* to innervate the striated muscle around the urethra and the external sphincter of the bladder. The pudendal nerve also contains sensory fibers from the posterior urethra.

Physiology of Micturition.—For many years it has been accepted that there is reciprocal innervation of the bladder, i.e., that the parasympathetic contracts the detrusor muscle and inhibits the internal sphincter; conversely,

Fig 447 —Extrophy of the bladder

A, Case 1 At the age of 3 years the ureters were transplanted to the sigmoid and the bladder excised.

B, Case 2 At the age of 2 years the lateral walls of the bladder were mobilized and the bladder closed over the balloon of a Foley catheter. The defect in the abdominal wall was closed by covering it with a flap of rectus fascia and skin. Reconstruction of the urethral sphincter has not been attempted yet in this patient. Hugh Young reports a successful outcome by use of this procedure.

also joins it. This network provides intercommunication between the celiac, semilunar, and aorticorenal ganglia. At the level of the promontory of the sacrum the presacral nerve contains both afferent and efferent fibers.

The *parasympathetic* fibers arise from the sacral segments 2, 3, 4 and run through the hypogastric plexus. The proximal portion of the hypogastric plexus forms a nerve group which is motor to the bladder and causes con-

traction that the sympathetic contracts the internal sphincter and relaxes the detrusor. This view is no longer held. Anatomically there is no true sphincter at the bladder neck. The detrusor muscle of the bladder, i.e., the longitudinal layer, is continuous with the bladder neck, so that what has been called the internal sphincter is really simply the edge of the detrusor muscle. The circular muscular layer of the bladder is responsible for the maintenance

Fig. 418—Pathways responsible for normal micturition. Diagram shows sympathetic, para-sympathetic, and somatic nerve supplies of the bladder. Note that the parasympathetic fibers carry the impulses which are responsible for contraction of the detrusor muscle and that the pudendal nerve relaxes the external sphincter. The role of the sympathetic system in the act of micturition is somewhat indefinite.

Fig. 449—Anatomic relations of the urinary bladder, urethra, and rectum, showing sites of injury.

of adequate intravesical pressure. The sympathetic nerves play no part in micturition. They carry pain and temperature sensations only.

The act of micturition is essentially a spinal reflex. Distention of the bladder causes a desire to void. This stretch reflex is carried by the afferent fibers in the parasympathetic nerves to the sacral spinal cord and up the cord to the pons, subcortical, and cortical areas of the brain where involuntary and voluntary control, respectively, are normally situated. With the removal of voluntary control, the act of micturition is initiated by a contraction of the vesical muscle (i.e., detrusor or longitudinal muscle) via the *parasympathetics*. Once this contraction is fairly well established, the internal orifice of the bladder (bladder neck, "internal sphincter") opens, and the external sphincter (supplied by the pudendal nerve, i.e., somatic) relaxes (See also pp 292 and 293).

The Neurogenic Bladder

Immediately following serious trauma to the spinal cord in which there is spinal transection, a condition known as "spinal shock" ensues. This is a state of depression of the spinal reflexes in the segments caudal to the lesion. It is generally transient in character.

The actual mechanics of this condition are unknown, but it causes paralysis with loss of reflexes below the level of the lesion. The bladder is immediately affected as shown by the following conditions:

- 1 Atonicity of the bladder wall
- 2 Absence of reflex contraction of the detrusor
3. Failure of sensory impulses to the brain and motor impulses from it

The bladder distends to a large size and overflow incontinence occurs in 36 hours. The atonic bladder noted immediately after injury in the state known as *spinal shock* is the first of three merging but fairly well-defined stages of spontaneous recovery.

First Stage—This may last 1 day to 18 months. Overflow incontinence is the only type of urination to be expected. Cystometric studies during this stage show a large bladder capacity with low pressure and without evidence of reflex detrusor activity, i.e., atonic neurogenic bladder.

Second Stage—This is a variable period of time from days to months after the injury; a return of reflexes caudal to the injured segment usually takes place. It is manifested in the cystometrogram by higher intravesical pressure. Reflex contractions of the bladder wall occur, but they are of insufficient strength or duration to produce efficient emptying. The clinical picture is that of periodic overflow incontinence, i.e., autonomous neurogenic bladder.

Third Stage—Progression to a third and final stage of recovery depends upon the extent of the injury and upon whether (1) transection has been partial or complete, (2) level of injury, (3) general condition of the patient, (4) degree of infection in the bladder.

Treatment of Bladder in Spinal Cord Injuries

Immediate Care—

- 1 Repeated catheterization at intervals is condemned because severe infections ensue.
- 2 Indwelling urethral catheter, either with or without tidal drainage, is not to be recommended, except in cases where fairly prompt recovery is anticipated. A periurethral abscess is a frequent complication.
- 3 Suprapubic cystostomy is usually the treatment of choice. With the bladder draining well through a large suprapubic tube, infection can be controlled. The cystostomy should be as high as possible. Some objections to this type of immediate treatment have been raised, the claim being made that with prolonged drainage, fibrosis of the bladder occurs and the bladder capacity is permanently reduced. This, however, has never been proved.
- 4 Urinary antiseptics should be used, commencing at the time of the injury.

Late Care.—

- 1 Continue with mild urinary antiseptics throughout the period of treatment. The intention is to obtain a bacteriostatic rather than a bactericidal effect.
- 2 Introduce methods to prevent calculus formation, i.e., move the patient frequently from side to side; get patient up if possible; otherwise use a tilting board under the mattress.

3. Keep the bladder clean by repeated irrigations, using either a bulb syringe or tidal irrigator apparatus. Solutions of boracic acid, sulfonamides, or buffered citric acid solution. G, M, or L, may be used for irrigation.

4. Remove any calculi that form in either the bladder or kidneys.

5. When recovery appears to be taking place, as evidenced by a return of reflexes caudal to the injured segment and the showing of a higher intravesical pressure on the cystometrograph, the suprapubic tube can be removed and the bladder allowed to close. An indwelling urethral catheter may be of assistance at this time. Rarely is a secondary closure of a suprapubic wound required.

Final Stage.—Recovery to the final stage is often surprisingly satisfactory. If the lesion is one of the cauda equina, fairly good control of the bladder can be developed.

In many cases, fibrosis of the bladder neck occurs with resultant hypertrophy of the adjacent muscle. An hourglass type of bladder neck develops. This may be relieved by a transurethral resection in which successive pieces of tissue are removed from around the bladder neck. It is desirable to eliminate residual urine. Repeated resections may be necessary to accomplish this.

Many patients in spite of careful treatment continue to have a residual urine of 1-2 ounces. In these patients a catheter should be passed once a week and the bladder thoroughly irrigated, as stagnant residual urine is prone to become infected and form calculi.

(See Infections of the Bladder, pp. 862-870.)

(See Acute Urinary Retention, pp. 891-895.)

Rupture of the Urinary Bladder

An understanding of rupture of the bladder requires knowledge of the fascial attachments of this organ. It should be remembered that injury to the bladder is frequently associated with other injuries. The patient may have multiple bone injuries, including head injuries as well as a torn bladder, and be in a fairly advanced degree of shock. In this type of case, history taking, physical examination to determine the extent of injury, and treatment of the shock proceed concurrently. Radiologic investi-

gation usually follows as soon as it is feasible. In the author's opinion, an intravenous pyelogram series is useful, as it will show extravasation of dye from the bladder, if it is torn, and also outline the kidneys.

Ligaments of Bladder.—Each side of the bladder is connected to the tendinous arch of the pelvic fascia by a condensation of fibroareolar tissue which is often termed the lateral true ligament of the bladder.

Anteriorly, the same tissue forms two thickened bands on each side of the midline, termed the lateral and medial puboprostatic ligaments. The apex of the bladder is joined to the umbilicus by the remains of the urachus which forms the median umbilical ligament. From its superior surface the peritoneum is reflected in a series of folds which are sometimes termed the false ligaments of the bladder. The fascia in the anterior part of the perineum is divisible into a superficial fatty layer and a deeper membranous layer, the layer of Colles.

Etiology.—The types of trauma causing rupture:

1. Crushing injuries
2. Falls
3. Blows and kicks
4. Manual emptying of the bladder

Rupture of the urinary bladder is usually due to external violence when the bladder is distended. The bladder when contracted often escapes injury even in violent crushing accidents. Rupture of the bladder is more common in males.

Pathology.—It follows from the foregoing that four distinct types of injury to the bladder may occur.

1. *Avulsion of the bladder neck.* In this condition the pubic symphysis is suddenly and violently separated, tearing the bladder neck away from its ligamentous moorings to the pubis and pelvis. The pubic symphysis may snap back into place immediately after the blow, so that one may not suspect from the x-ray that it has been separated. Further, the bladder neck may escape injury even when there is wide separation of the symphysis.

2. *Perforation of the bladder by a spicule of bone during a crushing injury of the pelvis.*

This is almost always extraperitoneal, the perforation occurring below the peritoneal reflection. Urine and blood escape into the space of Retzius, spread upward toward the umbilicus and laterally to the ischial spines. If the rupture is on the anterior wall, extravasation about the vesical neck and between the bladder and rectum will occur. This causes chills, fever, tenderness, infection, sloughing, and gangrene.

3. *Intraperitoneal rupture of the bladder caused by a direct blow.* Forty per cent of bladder tears are intraperitoneal and 60% are extraperitoneal. An intraperitoneal rupture occurs when the posterosuperior wall of the bladder is torn (usually following a direct blow to a full bladder). Blood and urine extravasate into the peritoneal cavity, causing a peritonitis with abdominal distention, tenderness, rigidity, fever, and rapid pulse.

A

B

Fig. 450—A, X-ray showing separation of the pubic symphysis, fracture of the rami, and extravasation of dye into the retropubic space from the bladder which had been widely torn at the bladder neck. The patient had been run over by the double rear wheels of a six ton truck.

B, X-ray showing wide separation of the pubic symphysis and fracture of the rami without injury to the bladder. The patient, a ballet dancer, has been able to continue her dancing career.

4. *Rupture of a partially distended bladder across its base posteriorly following a blow.* This is also an extraperitoneal rupture.

Symptoms of Rupture of the Bladder.—Early symptoms are due to injuries. Late symptoms are due to extravasation of urine and infection.

Signs of rupture:

1. Shock
2. Helplessness, patient unable to walk or walks with difficulty
3. Partial or complete inability to void

6. The passage of a catheter with the injection of a measured amount of fluid re-measured on its return not a reliable test.

7. Evidence of extravasation of dye in a cystogram.

8. Cystoscopic examination, which may reveal the tear.

Treatment.—

1. Combat the shock and hemorrhage which is most important.

2. Explore the bladder by suprapubic cystotomy and provide drainage. This should be done even in doubtful cases.

Fig 451.—Diagram showing varying anatomic relations of bladder when empty, distended, and ruptured

4. Blood at the urethral meatus
5. Ecchymosis, contusions, and hematoma of lower abdomen, pubes, genitalia, and thighs

Diagnosis.—Diagnosis is made on the following:

1. History
2. Shock
3. Local pains, tenderness, and swelling
4. Inability to void
5. Blood in urine

3. If the tear is intraperitoneal, open the peritoneal cavity, mop up any free fluid, and drain the peritoneum separately from the bladder.

4. If the tear is extraperitoneal, drain the bladder and all the extravascular areas of extravasation.

Prognosis.—The prognosis is good if the injury is recognized early and the bladder is drained.

GENITOURINARY SYSTEM

Tumors of the Bladder

Classification

- I. Papillary
 - Papilloma
 - Papillary carcinoma
- II Solid
 - Transitional cell carcinoma
 - Squamous cell carcinoma
 - Adenocarcinoma (mucus secreting)
 - Anaplastic carcinoma
- III Mesoblastic tumors
 - 1 Benign growths
 - Fibroma
 - Myoma
 - Myxoma
 - Angioma
 - 2 Malignant
 - Sarcoma
 - Rhabdomyosarcoma

Theories of Origin.—The cause of cancer is unknown. There are several theories as to the cause of bladder tumors

- 1 Virus infections
- 2 Chemical irritation

3 Occupational, e.g. bladder tumors in aniline dye workers and the scrotal cancers of chimney sweeps

4. The influence of the constant flow of urine

Papilloma—Papillomatosis

Papillomas of the bladder may be single or multiple. When several small growths occur together or in rapid sequence, the condition is termed papillomatosis.

They may be found anywhere in the urinary bladder. The majority are situated on the trigone or at the junction of the trigone and bladder. They frequently occur at the ureteral orifices. They are less common on the lateral walls.

Pathology.—

Gross.—The papilloma appears as a pedunculated villous or papillary growth arising from the mucous membrane. It may be sessile, but this type is less frequent. Some papillomas have a wartlike surface, while others are almost smooth. The size of the growths varies considerably, some are small and may remain

Fig 452 A Cystogram showing marked filling defect of left side of bladder due to extensive bladder tumor
 B Cystogram showing filling defect in right side of bladder due to pedunculated tumor protruding into bladder

so over long periods. Both the pedunculated and the more malignant sessile tumors may attain considerable size.

Microscopic.—A typical papilloma shows multiple connective tissue stalks containing thin walled blood vessels, thus the tendency to spontaneous bleeding. Glandular or cystic formations may be present, or an inflammatory process may cause a leukocytic invasion of the central stalk, but these should not be mistaken for a malignancy.

Histologically there is no difference between the single and multiple forms. Ninety per cent are papillary in character. Many are benign and may remain so for years. The marked tendency to malignancy of the so-called benign papilloma and the ill defined demarcation that exists between it and malignant growths have led many pathologists to regard all vesical papillomas as potentially malignant, even if initially they can be proved to be benign.

Papillary Carcinoma

Papillary carcinoma is a papilloma with malignant infiltration at the base and in the underlying bladder wall. It is the most common type of vesical carcinoma. The American Registry of Pathology classifies all papillomas as papillary carcinomas.

Squamous Cell Carcinoma (Flat Infiltrating Carcinoma)

Squamous cell carcinoma is less common than papillary carcinoma. It is a flat sessile growth with a cornifying epithelium which projects only slightly into the vesical cavity but invades deeply and spreads laterally. It is deeply and rapidly infiltrating at the outset. It is the most malignant of the vesical neoplasms and is radioresistant.

Pathology.—

Gross.—This carcinoma appears as a shallow red malignant ulcer surrounded by a hard everted border.

Microscopic.—Relatively thick connective tissue is seen between the cell nests, as distinguished from the papillary type of carcinoma. The cells progress along the surface of

the bladder and at the same time invade the deeper layers of the wall.

Leukoplakia is commonly regarded as a precursor of squamous cell carcinoma.

Adenocarcinoma and Adenoma

Adenocarcinoma, primary in the bladder, is a rare, highly malignant neoplasm closely resembling adenocarcinoma of the prostate gland. It arises chiefly from the paraprostatic glands that are sometimes present in the wall of the male trigone and in remnants of the urachus in the apex of the bladder. It may occur as a flat growth, showing extensive infiltration of the bladder wall, or it may have a thick pedicle and project into the bladder as a pedunculated tumor. It ulcerates early.

Interstitial Carcinoma

An interstitial carcinoma growing in the wall of the bladder may not produce any symptoms except a decreasing bladder capacity. The bladder is rigid and will not stretch under anesthesia when one tries to introduce fluid forcibly. The growth is usually located in the vicinity of the bladder neck or at the apex. The structure varies greatly. They are usually small in size and sessile, though some are pedunculated.

Mesoblastic Tumors

Benign—may be fibroma, myoma, myxoma, angioma, hemangioma, or neurofibroma.

Sarcoma—is rare and fast growing.

Metastases

Metastases of bladder tumors occur in 10-40% of all cases. Metastasis may occur as follows:

1 By direct local extension to the prostate, pelvic tissues, to the kidney via the ureter, to the penis or vagina.

2 By the lymphatic or blood stream to the long bones, liver, lungs, and regional lymph nodes; recurrence after removal fairly common.

Symptoms.—Painless hematuria is present in 80% of the patients. Frequency, dysuria, pyuria, and interruption of the urinary stream are other predominant symptoms.

Diagnosis.—Diagnosis is made on the following.

1. History
2. Physical examination
3. Examination of urine for malignant cells with special stains
4. Cystoscopy—the tumor viewed directly
5. Cystogram—filling defect may be seen
6. Biopsy

Treatment.

1. Fulguration or coagulation of the tumor either transurethraly or suprapubically, depending upon the size
2. Local resection of the tumor-bearing area with 1 cm of healthy appearing tissue around it
3. Local resection plus the implantation of radon seeds
4. Radiation both externally and by opening the bladder and inserting an x-ray tube—produces a severe cystitis without appreciably affecting the tumor
5. Total cystectomy with transplantation of the ureters to either the bowel or skin
6. Permanent suprapubic cystostomy

The Use of Isolated Ileal Segments as Bladder Substitutes

The use of an isolated segment of ileum as a substitute bladder has proved of value in dealing with far-advanced cases of carcinoma involving the urinary bladder, rectum, and cervix, or in total pelvic exenteration and prior to cordotomy or alcohol injection of the spinal canal for the relief of intractable pelvic pain due to carcinoma.

Bricker's method of isolating 8-10 inches of ileum approximately 8" from the ileocecal valve, closing the proximal end and transplanting the ureters to the isolated loop by mucosa-to-mucosa anastomosis, and then bringing the proximal end of the loop out onto the skin surface has proved most useful. We have used this in far-advanced cases of carcinoma of the cervix where the pelvis is "frozen," in vesical-vaginal-rectal fistulas due to carcinoma of the cervix, in total pelvic exenteration, and in cases of recurrent carcinoma of the urinary bladder which could not be controlled by local excision, radiation therapy, or cobalt

therapy. In the latter cases the bladder and prostate are removed in toto at the time the substitute bladder is constructed. The results in all types of cases mentioned have been most gratifying

Metaplasia of the Bladder

The epithelial cells of the urinary tract are particularly prone to proliferation and metaplasia. After minimal injuries, such as an infection in the bladder or a calculus, epithelial changes may occur and result in projection of buds from the inferior layer of epithelium of the bladder into the submucosa. These are known as *Brunn's epithelial nests* which may become vacuolated, forming cysts. This is known as *cystitis cystica*. (Ureteritis cystica or pyelitis cystica represents the same process going on in the ureter or the pelvis of the kidney.) Either of these conditions may be a precursor of leukoplakia and, in turn, of *squamous cell carcinoma*.

In other "Brunn nests," changes may occur that result in gland formation. The epithelial cells lining these glands are capable of secreting mucus. This process is known as *cystitis glandularis* and may undergo metamorphosis into a mucus-secreting *adenocarcinoma*.

Ulceration of the Bladder

May be due to the following:

1. Interstitial cystitis (submucous fibrosis)
2. Infections other than tuberculosis
3. Carcinoma
4. Radiation

Interstitial Cystitis.—(Synonyms: Hunner's ulcer, submucous fibrosis, elusive ulcer.) This is characterized by single or multiple minute lesions of the bladder wall. Ulcers are not always present. The etiology of this disease is entirely unknown. It is much more common in females. The lesions are frequently located on the dome of the bladder. Pathologically the mucosa is flattened and there is submucous fibrosis. The clinical picture is variable, but usually there is pronounced frequency and suprapubic pain. Microscopically the urine is normal except for a few scattered red blood cells in it.

The treatment of this condition is often extremely difficult and has led to a wide variety of methods:

1. Dilatation of the bladder under spinal anesthetic
2. Instillation of Novocain anesthetic into the bladder, followed by silver nitrate
3. Fulguration of the ulcers
4. Resection of the bladder, removing the ulcerated areas

Infectious Ulceration.—Ulceration associated with pyogenic infection of the bladder may occur but is uncommon. Ulcers may be single or multiple and disappear when the infection is eliminated. Ulceration in tuberculous cystitis is relatively common. (See section on Genitourinary Tuberculosis.)

Carcinoma.—The ulceration associated with carcinoma of the bladder is readily recognized. It is slow growing, clear cut, and appears punched out. Any ulcer of the bladder that becomes chronic should be suspected of malignancy.

Radiation Ulcer.—A radiation ulcer of the bladder may follow deep x-ray therapy to the pelvic region or follow the implantation of radium into the cervix. The actual ulceration may not commence until months up to 12 years after the exposure. The ulcer is indolent, slow growing, and may progressively increase in size. The underlying pathologic process is an endarteritis, with obliteration of the vessels. The treatment is symptomatic. Installations of oil into the bladder give some relief of symptoms. Cerutin appears to have a beneficial effect on cases recognized early, before actual ulceration has occurred.

Diverticulum of the Bladder

A diverticulum or saccular ballooning out of the bladder wall is a relatively common urologic finding. It may vary in degree from multiple shallow sacculations, involving most of the bladder wall, to single or multiple sacs connected to the bladder by a narrow opening. They may reach a considerable size. A diverticulum with a narrow neck drains poorly and almost always contains stagnant infected urine. The causes of diverticulum may be

1. Congenital weakness of the bladder wall

2. Obstruction to the urinary outflow (prostatic obstruction, urethral valves, etc.)

It is probably more nearly correct to say that a diverticulum is always due to obstruction of the outflow. A diverticulum may be complicated by the presence in it of a calculus or a tumor.

Symptoms.—The diverticulum itself rarely produces symptoms. It is usually a coincidental finding at the time of investigating a patient for symptoms of urinary obstruction. Pyuria is a common finding.

Fig. 453.—X ray showing diverticulum of bladder

Treatment consists of the following:

1. Removing the diverticulum or the mucous membrane lining it
2. Removing the cause of the obstruction (prostate, vesical neck contracture, valves in the urethra, etc.)
3. For a calculus or a tumor in a diverticulum, removing the diverticulum

Vesical Calculus

Calculi in the urinary bladder may be single or multiple; they vary from the size of a garden pea to that of a full-term fetal head. They vary in shape from round to jackstone

and may be smooth or irregular. They are most commonly due to or associated with the following:

- 1 Infection
- 2 Obstruction of the bladder neck, usually associated with infection
- 3 Foreign bodies in the bladder
- 4 Neurogenic bladder

The general etiology of calculi has been discussed on page 870. In the obstructed bladder with its concomitant residual urine and associated infection, the *Bacillus proteus* is frequently the offending organism. A foreign body in the bladder, such as a surgical sponge left after an operation on the bladder, or a broken tip of a filiform dilator, is certain to produce a calculus. Many patients with a neurogenic or cord bladder following a spinal cord injury have some residual urine, which even though small in amount becomes heavily infected, thick, and foul, and frequently causes stone formation. This can usually be prevented by the passage of a catheter and bladder lavage once a week.

The chemical composition of a vesical calculus is generally mixed. Different compositions produce layers so that the stone presents a lamellated appearance in cross section.

Composition of Vesical Calculi.—

- 1 Uric acid, urates. The stone is flat or ovoid, yellow to dark red in color, friable, and may be either rough or smooth.
- 2 Phosphatic calcium phosphate, magnesium phosphate, ammonium phosphate. The stone is oval or round, white in color, and may be friable.
- 3 Calcium oxalate. The stone is round, brown to black in color, has a mulberry surface, and is extremely hard.

Complications of Vesical Calculi.—

- 1 Obstruction of bladder neck
- 2 Infection
- 3 Ulceration of bladder
- 4 Impaction of the stone in the bladder neck, diverticulum, or urethra

Symptoms.—

- 1 Pain radiating to the glans penis, present on voiding and on exercise
- 2 Frequency and urgency
- 3 Hematuria
- 4 Interruption of the urinary stream
- 5 Retention of urine

Diagnosis.—Diagnosis is made on the following.

1. History
2. Urinalysis, examining especially for red blood cells
- 3 X-ray evidence of calculus in the bladder—about 95% of bladder calculi contain calcium and are visible radiologically.
- 4 Cystoscopic examination with direct visualization of the calculus

Fig. 451.—Plain film of bladder area showing fairly large vesical calculus

Treatment.—

- 1 Crushing of the stone instrumentally through the urethra if it is not too large (litholapaxy)
- 2 Removing the stone by opening the bladder suprapubically (cystolithotomy)
- 3 Removal of the calculus by perineal section

Foreign Bodies in the Bladder

A wide variety of foreign bodies may be found in the urinary bladder. The commonest are surgical sponges, broken off tips of filiform dilators, and the wide variety of foreign bodies introduced by sexual perversities. Such objects may be toothpicks, lead pencils, chewing gum, hairpins, etc.

The presence of a foreign body in the bladder produces an intense acute inflammation with all the symptoms of an acute cystitis previously described. The foreign body can frequently be removed by instrumentation

through the urethra. If this is not possible, suprapubic cystotomy is done and the foreign body removed.

Extravasation of Urine

(See page 883)

PROSTATE GLAND

Anatomy.—The prostate gland is a musculo-glandular organ, which surrounds the neck of the bladder and the first portion of the urethra in the male. It is situated below the pubic symphysis and behind the inferior fascia of the triangular ligament. Its posterior surface rests on the rectum. The urethra traverses its length. The seminal vesicles which are situated on the posterior surface empty into the ejaculatory duct on each side in the prostatic urethra. The prostatic ducts also open into the prostatic urethra.

The prostate gland is made up of three lobes, two lateral and a middle, which give the gland a horse collar shape. It normally weighs about 20 Gm. Attached to the prostate are the puboprostatic ligament and the inferior fascia of the urogenital diaphragm (triangular ligament). It is surrounded by a firm fibrous capsule.

The blood supply of the prostate is derived from the internal pudendal, vesical, and middle hemorrhoidal arteries.

The prostatic capsule is surrounded by a rich plexus of veins which terminate in the internal iliac vein.

Embryology.—At about the 35 mm stage a series of buds arranged in five groups, arising from all sides of the urethra and from the upper pelvic portion of the definitive urogenital sinus, grows into the dense surrounding mesenchyme which later differentiates into the muscular and connective tissues of the gland. The posterior lobe rudiment develops as a separate capsule.

Normal Physiology of the Prostate.—

Prostatic Secretion.—The daily secretion averages 0.5–2.0 ml. This is discharged through the ducts into the urine. Prostatic secretion contains, on chemical analysis, organic and in-

organic substances, sodium, potassium, calcium, protein, glucose, ascorbic acid, citric acid, acid phosphatase, alkaline phosphatase, and cholesterol.

Acid phosphatase is present in very small amounts before puberty but increases greatly during the sexual life. In carcinoma of the prostate, acid phosphatase appears in large amounts in the blood when the growth extends beyond the capsule of the gland.

The prostate does not have any internal secretion.

There is a large amount of lipoid fluid in the prostatic secretion in the form of corpuscles, which may be mistaken for pus cells.

Prostatic fluid is alkaline. It apparently contains no secretion essential to fertilization. Young produced pregnancy in guinea pigs by insemination with sperm from isolated epididymes.

Effects of Endocrine Therapy on Prostate Gland.—There is no verified clinical or experimental evidence that endocrine therapy has any effect on either the normal or hypertrophied adult prostate gland of man.

There is no positive clinical or experimental evidence that administered androgen or estrogen causes carcinoma in the prostate.

When estrogen is administered to patients with carcinoma of the prostate, there appears to be retardation of the growth, which may decrease in size.

Conditions of the Prostate Gland

Anomalies

Absence of the prostate gland or congenital cyst rarely occurs. A congenital cyst may be removed surgically.

Prostatic Injuries

These may be due to the following:

1. External injury, e.g., falling astride a picket fence. Rupture of the urethra is a frequent complication and is the usual cause of a stricture located in the posterior urethra
2. Internal injury caused by the passage of instruments. A false passage may be made when passing a sound
3. Operative injury, which is very rare. This may occur during operations on the perineum

Prostatic Calculi

Calculi form in the prostate gland only when an infection has been present for a prolonged period. The calculi are usually multiple and vary in size from that of grape seeds to the size of marbles, completely replacing the glandular structure so that only the capsule is left. There may be hundreds of smaller calculi or only a few large ones.

They may not cause any symptoms or may cause typical symptoms of prostatic obstruction. They can frequently be palpated rectally and visualized on x-ray.

Treatment.—If the calculi are small, they are removed by doing a transurethral prostatic resection. If they are large and fill the entire prostatic capsule, they should be removed surgically, either by the suprapubic, retropubic, or perineal route.

Prostatism (Synonym: Benign Prostatic Hypertrophy)

Definition.—Prostatism is a term used to describe a condition in which urinary symptoms develop as the result of obstruction at the bladder neck due to either an increase or decrease in the size of the prostate gland. It is caused by hyperplasia of the gland (median bar), sclerosis of the gland (median growth (carcinoma)).

Age Incidence.—Prostatic obstruction occurs with increasing frequency in each decade, from the age of 40 onward. The incidence is 40-49 (9%), 50-59 (20%); 60-69 (35%); 70-79 (43%).

Theories of Origin.—The so-called prostatic hypertrophy is neither prostatic nor hypertrophy. It is hyperplasia. It consists of tissue

which arises from the epithelium and the ducts surrounding the verumontanum on the floor of the urethra. The hyperplasia consists of nodules made up of fibromuscular and glandular tissue. The former arises from an analogue of the müllerian duct system and the latter from the prostatic duct epithelium.

Chronic infection or vascular changes in the prostate gland and hormonal imbalance have also been thought to be responsible for the gradual increase in the size of the gland. Castration, or the administration of estrogenic substances, does not result in reduction of the hyperplastic process.

Symptoms of Prostatic Obstruction.—The first symptom of prostatic obstruction is the gradual onset of difficulty in starting the urinary stream, followed by increased frequency, nocturia, hesitancy of the urinary stream, urgency, and, in many cases, hematuria. Incomplete retention develops (i.e., residual urine) and eventually a complete retention with inability to void. Some cases show incontinence due to stretching of the internal sphincter by the increased size of the prostate. Sexual debility is a common complaint. There may be pain either in the suprapubic region or the lower lumbar region posteriorly.

Diagnosis of Prostatic Obstruction.—A diagnosis of prostatic obstruction is made on the history of gradually increasing urinary difficulty and the symptoms listed above. On rectal examination an enlarged prostate is palpated. The patient is catheterized immediately after voiding to determine the amount of residual urine present. On cystoscopic examination the enlarged prostate is visualized at the bladder neck. A cystogram will also frequently show an intravesical protrusion of the enlarged prostate.

Treatment.—There are four accepted surgical methods of treating enlargement of the prostate gland.

1. **Transurethral resection.** In this operation successive pieces of tissue are removed from around the bladder neck and the prostate itself by means of a resectoscope. The gland is not as completely removed as in the other types of operation.

2. **Suprapubic prostatectomy.** This may be carried out in either one or two stages. A

Plate 40.—Anatomy of the Prostate Gland.

Plate 42.—Prostatic Obstruction Producing Dilatation of the Ureters and Renal Pelvis.

skin incision is made in the suprapubic region of the lower abdomen, the bladder opened, and a drainage tube inserted into the bladder. The prostate is removed at the time of opening the bladder or at a subsequent operation 2 or more weeks later. If the patient is debilitated or uremic, removal of the prostate is deferred until the patient improves.

3 *Retropubic prostatectomy.* The prostate gland is removed through a skin incision made in the lower abdomen. The entire procedure is done outside the bladder through the prostatic capsule, without actually opening the bladder.

4 *Perineal prostatectomy.* The prostate gland is removed through an incision in the perineum above the anus which exposes the gland from the outside, without entering the bladder.

Carcinoma of the Prostate

Incidence.—Carcinoma of the prostate gland affects 5% of all men who reach the age of 60 years. One of every five prostate glands removed for benign hyperplasia shows carcinoma histologically.

Carcinoma usually begins in the posterior lobe but may be found anywhere in the gland.

Diagnosis of Carcinoma of Prostate.
This is based on the following:

1. Rectal examination. The gland is usually irregular in shape and stony hard in consistency. The hardness may be limited to a small area of the gland or involve the entire gland, even extending out laterally into the ligaments and upward into the seminal vesicles. Such a gland is referred to as "fixed" or "frozen."

2. Examination of the prostatic fluid by special stains for carcinoma cells is unreliable even in proved cases of carcinoma.

3. Biopsy of the prostate gland establishes absolute proof of carcinoma but is occasionally misleading, since the biopsy may fail to show carcinoma that is present elsewhere in the gland.

4. X-ray evidence of metastases in the bones or chest.

5. Elevated acid serum phosphatase.

The Significance of the Acid Serum Phosphatase in Prostatic Carcinoma.—A phos-

phatase is an enzyme which splits organic phosphorus compounds to give free phosphate ions. Phosphatases differ in the pH at which they show their maximum activity and accordingly are known as *acid* or *alkaline* phosphatases.

Normal human prostatic tissue is the only tissue in the body that is rich in *acid phosphatase*. The concentration in adult human prostatic tissue is 500-2,500 units of activity per gram fresh tissue as compared with less than 5 units of activity at pH 4.9 for kidney, liver, duodenal mucosa, and bones. The enzyme normally is excreted in the prostatic component of the ejaculate. Its exact function is unknown. In prostatic carcinoma, when the capsule of the gland ceases to be intact and the growth infiltrates into the surrounding soft tissues or metastasizes to bone, the "acid" phosphatase which is normally below 3 units/100 ml of serum rises. Values above 6 units/100 ml are pathognomonic of metastasizing prostatic carcinoma.

When the secretory stimulus of the androgens is removed by castration, there is a rapid fall in the *acid* serum phosphatase by 45% within 48 hours, 75% within 2 weeks, followed by a transient gradual rise, and, finally, a prolonged decline until after 2-3 months, equilibrium is reached. In those patients who do particularly well clinically, the acid serum phosphatase remains at these new lower levels. A persistently high postoperative acid phosphatase after castration is due to stimulation by androgens from extragonadal sources (adrenals).

The Significance of the Alkaline Serum Phosphatase in Prostatic Carcinoma.—There is no correlation between the acid serum phosphatase and alkaline serum phosphatase in patients with metastasizing prostatic carcinoma. The amount of alkaline phosphatase in the blood is an indication of the activity of the bone defense. After castration, the early changes are not consistent, but after a latent period of 2-3 weeks there is a rise of the alkaline phosphatase attributable to the osteoblastic activity in the healing of skeletal metastases. As the extra bone formation finally decreases, the serum alkaline phosphatase level declines to normal.

Symptoms of Carcinoma of the Prostate.—

1. Prostatism—causing symptoms of obstruction
- 2 Pain—due either to direct extension in the pelvis and involvement of nerve sheaths or to metastases in the spine or pelvic bones

Treatment.—

- 1 Radical perineal prostatectomy in cases recognized early This is the only method of obtaining a cure The prostate, seminal vesicles, and bladder neck are removed en masse
- 2 Surgical castration
- 3 Medical castration—by giving stilbestrol 5 mg per day orally for 2 weeks, then 5 mg twice a week thereafter

Some surgeons prefer to bombard the prostate with large doses of estrogen, thereby causing the gland to shrink, and to follow this by a radical perineal prostatectomy. It is claimed that an inoperable carcinoma is thereby converted into an operable one

In patients suffering excruciating pain from metastases, spectacular and complete relief of pain is obtained, in most cases within 72 hours, by surgical castration

Chronic Prostatitis and Nonspecific Urethritis

Nonspecific urethritis and prostatitis are frequently erroneously regarded as being a chronic form of gonorrheal urethritis. Either or both may exist without a previous attack of gonorrhea. Chronic nonspecific urethritis alone is rare, whereas chronic prostatitis alone is common. Fifty per cent of cases with chronic prostatitis or urethritis give a previous history of gonorrhea, 36% have had what was diagnosed as a nonspecific urethritis, and 14% have never had any previous symptoms, the discovery of a large number of pus cells in the prostatic fluid being a coincidental finding. In this latter group the infection is comparable to an upper respiratory infection, except that the infection settles in the prostate gland which, because of its dependent position in the body with consequent poor drainage and complex histologic architecture, affords an ideal environment to harbor infection.

Symptoms.—The patients' symptoms are urethral discharge, frequency, burning, terminal hematuria, vague perineal discomfort, and backache. In the group of cases in which

there is a previous history of gonorrheal or nonspecific urethritis, urethral discharge is usually present and is the main symptom in over 70% of cases. In those cases in which there is no previous history of urethritis, a urethral discharge occurs in approximately 21%. Pyuria without symptoms is a common finding.

Origin of Condition.—The majority of these patients give a history of alcoholism and sexual excess immediately preceding the onset or recurrence of symptoms. This appears to be a factor in lowering the resistance of the urethra and prostate by the following:

- 1 Favoring subsequent invasion by organisms from the host which are normally nonpathogenic, via the lymphatics or possibly the blood stream
- 2 Exacerbation of a previous prostatitis in which there is still some residual infection present
- 3 Organisms from a carrier at the time of intercourse, which may not be pathogenic to the carrier
- 4 Virus

Bacteriology.—The urethral discharge when cultured shows staphylococci in 55% of cases, diptheroids 10%, mixed staphylococci, streptococci, and micrococci 32%, trichomonas vaginalis 2%, and gonococci 1%. Protozoa may also be found in the urethral discharge.

Diagnosis.—A diagnosis is made on the following:

- 1 The history and symptoms
- 2 The presence of urethral discharge
- 3 The three-glass urinalysis
- 4 Examination of the prostatic fluid

The symptoms of urethral discharge, frequency, burning, terminal hematuria, and vague perineal discomfort are almost pathognomonic of the condition. Palpation of the prostate is often misleading. In some cases the gland is firm and fibrosed; in others it is soft and normal to palpation. Examination of the prostatic fluid obtained by massage is essential to establish a diagnosis.

Criteria of Cure.—

- 1 The patient must be entirely free of symptoms, and there must be no urethral discharge
- 2 The three-glass urinalysis is normal.
- 3 The prostatic fluid on culture is negative for gonococci.

4 The number of pus cells in the prostatic fluid is reduced to below 5 per high power field

5 Re-examination in 3 months' time confirms these findings

Treatment.—

1. Prostatic massage—twice weekly—until apparently cured.

2 Dilatation of urethra—stricture of the urethra even though not severe and a small external urinary meatus are the two commonest causes of failure to eradicate the infection. A normal urethra should accommodate a Fr. No 26 sound without difficulty.

3 Urethral irrigations are frequently helpful, particularly if there is much urethral discharge. Any one of several solutions may be used

a Protargol— $\frac{1}{4}$ of 1%

b Potassium permanganate—1:12,000 solution

c Silver nitrate—1:10,000 solution

d Chemotherapy

a Penicillin—300,000 units of penicillin G intramuscularly daily for 14 days

b Streptomycin, 1 Gm. daily for 14 days

c Aureomycin—according to weight

d Chloromycetin—according to weight

e Terramycin

f Atabrine, 90 mg t.i.d.

g Arsenic

Prostatic massage is considered to be an essential part of the treatment. When this is deleted from the program of treatment, the percentage of cases "apparently cured" drops from 75% to 10%

Treatment may require weeks or even months to complete. Recurrence is unfortunately common and suggests that the disease was not entirely eradicated by treatment, despite clinical and laboratory tests to the contrary

Prostatic Abscess

Etiology.—Prostatic abscess may be single or multiple and follows—

1. Acute gonorrhoeal urethritis (uncommon now)

2. Any nonspecific prostatitis

3 Traumatic instrumentation

4 Urethral stricture

5 Metastatic infection, as a complication of pyemia, typhoid fever, influenza, carbuncles, or boils

Symptoms.—The symptoms are pain in the perineum, fever, chills, and increasing difficulty in voiding which may progress to acute retention.

Prognosis.—The prostatic abscess may rupture into the urethra, rectum, perineum, or bladder.

Treatment.—

1 Incision and drainage of the abscess through the perineum. A perineal urethrotomy may be done at the same time and an indwelling catheter inserted.

2 Chemotherapy. Usually one of the antibiotics can be used, the type depending upon the bacteriology of the infection.

Tuberculosis of the Prostate

(See page 878.)

PENIS AND URETHRA

CONDITIONS OF THE PENIS

1 Congenital anomalies (double phallus, hypospadias, epispadias)

2 Phimosis, paraphimosis, balanitis

3 Venereal warts (condylomata acuminata, condylomata lata)

4 Chancre, chancroid, lymphogranuloma venereum, granuloma inguinale

5 Plastic induration (Peyronie's disease)

6 Priapism

7 Tumors

Congenital Anomalies

Double phallus is a rare anomaly.

Hypospadias is a congenital defect of the anterior urethra. The urethra is incompletely formed so that it opens on the undersurface of the penis, in the scrotum, or perineum. This is a relatively common anomaly. Hypospadias is classified as first, second, or third degree, depending upon the site of the urethral opening. The first degree opening is just behind the normal site of the external urinary meatus

In hypospadias a hood or cap of foreskin overhangs the glans penis. This should be preserved for future use in plastic procedures on the penis. Associated with the hypospadias there is a marked chordee or downward curvature of the penis, caused by replacement of the corpus cavernosum urethrae by fibrous tissue. Correction of the hypospadias is achieved by a series of plastic operations. The first stage consists of removing the scar tissue causing the chordee and straightening the penis. At the second operation a new urethra is formed by using full or split-thickness skin grafts or by means of a tube pedicle graft. The urethra is buried, covered, and finally connected to the normal urethra. Before such operations are undertaken, the urinary stream is diverted by suprapubic cystostomy. The end results are usually satisfactory.

Epispadias is a rare anomaly. The urethra is situated above the corpora cavernosa and lies open on the dorsal surface of the penis. The roof of the urethra is lacking throughout part or all of its length. This condition is usually associated with exstrophy of the bladder which may be partial or complete. Surgical correction of the deformity with construction of a urethra and closure of the bladder can be carried out, although incontinence is likely to persist. An alternative treatment is to transplant both ureters into the bowel and excise the bladder.

Phimosis

Phimosis is a condition of the foreskin which prevents its retraction. The prepuce is long and redundant. The acquired form is seen in adults and is due to irritation which may be inflammatory, traumatic, or consequent to incontinence associated with prostatic obstruction or overflow from the bladder.

In the acute stage irrigations under the foreskin with potassium permanganate or boric acid solution hasten recovery. If the foreskin is sectioned along the dorsum of the glans penis, the healing process is further accelerated. When the acute inflammation subsides, circumcision is indicated to prevent recurrence.

Paraphimosis

Paraphimosis is strangulation of the foreskin by the circular constriction of the re-

tracted prepuce which can no longer be reduced. It frequently accompanies acute inflammatory conditions, such as gonorrhea, chancre, and chancroid. It requires immediate relief either by digitally reducing the glans through the ring or by surgical division of the constricting band (dorsal slit). Gangrene results if the strangulation is not relieved. Paraphimosis also occurs in the aged, when the elasticity of the foreskin is lost.

Balanitis

Balanitis is a superficial inflammation of the glans penis. In most cases the undersurface of the prepuce is also affected, producing a balanoposthitis. The glans penis becomes damp, red, and itchy. An exudate forms. Treatment consists of local cleanliness. Circumcision during quiescence is desirable so that debris and moisture can no longer collect beneath the foreskin.

Venereal Warts

Condylomata acuminata are single or multiple wartlike eruptions on the skin of the external genitalia. They are variable in shape and are most commonly situated around the corona (i.e., the sulcus proximal to the glans penis) and on the prepuce. They are not due to venereal disease but are most common due to excessive moisture. They are removed by treating them with aqueous podophyl 25%, silver nitrate stick, or by electrofulguration. Clinically the results are much more satisfactory if the redundant foreskin with attached warts is excised and the remaining warts fulgurated.

Condylomata lata, the warts of secondary syphilis, are moist broad warts that frequently fuse and cover an extensive area, even extending as far as the anus. Diagnosis is based on dark-field and serologic examination. Treatment consists of local cleanliness and antisyphilitic therapy.

Chancre, Chancroid, Lymphogranuloma Venereum

Syphilis (chancre) is the result of infection by the *Sprochaeta pallida*. In the primary

Plate 44.—Condylomata Acuminata (Venereal Warts).

Plate 45 —Carcinoma of the Penis.

Courtesy Marshall, Victor F. The Diagnosis of Genito-Urinary Neoplasms, American Cancer Society, Inc.

stage, at the end of the incubation period, a chancre appears on the glans penis or shaft of the penis, at the corona, frenulum, or inside the prepuce. The lesion is painless. It is commonly single but may be multiple. The chancre has a hard, indurated, raised edge, like a button, with an intensely red ulcerated center. The inguinal nodes are enlarged, firm, and discrete (shotty). The treatment is antisyphilitic therapy.

Chancroid (soft chancre) is a venereal ulcer usually situated on the external genitalia and caused by the Ducey-Unna bacillus. Uncleanliness and dirty habits favor its development. The ulcers are irregular with a gray base and undermined edges. Suppurative inguinal adenitis may occur and is called a bubo.

Diagnosis is made on the appearance of the ulcer, the clinical course of the disease, the skin test (commercial antigen injected intradermally), and the presence of the Ducey bacillus. Syphilis must be excluded.

Treatment consists of local cleanliness and sulfonamide therapy. Cauterization of the ulcers with nitric acid has been recommended.

Lymphogranuloma venereum is a specific disease caused by a filtrable virus. A primary sore appears 2-7 days after exposure, usually on the corona in the male and on the posterior vaginal wall or posterior cervical wall in the female. The initial lesion is vesicular or nodular. Soon there is swelling in the inguinal nodes. The overlying skin breaks down and sinuses form. *Diagnosis* is made upon the clinical appearance and the Frei cutaneous test.

Antimony is specific for this disease. Aureomycin is also effective.

Granuloma inguinale is a lesion which begins as a papule in the groin, perineum, vulva, or prepuce. It soon ulcerates and invades the surrounding tissues. It does not show any tendency to heal. It is caused by a specific organism called the Donovan body (*Bacillus mucosus capsulatus*). Secondary infection and erosion cause marked deformity of the organs. A diagnosis is made by the presence of Donovan bodies. Specific treatment is the intravenous administration of antimony and potassium tartrate. Fuadin is also effective.

Plastic Induration of the Penis (Peyronie's Disease)

The induration is due to fibrous infiltration of the penis which begins in the septum between the corpora cavernosa. It may extend into any part of the penis and finally reaches Buck's fascia and the tunica albuginea, where it can be felt as hard indurated plaques. These plaques and fibrosis cause deformity of the penis during erection and marked pain. The etiology is unknown.

Various forms of treatment have been recommended, including radiation therapy, excision, plastic procedures, etc. The results are moderately satisfactory. Recently the weekly injection of 1 ml of Hydrocortone F directly into the plaque has been recommended. Although the number of patients so treated is still small, the results appear to be superior to any of the other forms of therapy.

Priapism

Priapism is prolonged involuntary erection of the penis without sexual desire. This is an uncommon condition and difficult to treat, as it does not respond to medication. It may occur at any age but is more common in young adults. There is usually some serious underlying disease, such as leukemia, syphilis, neurologic disorders, or malignancies. Treatment consists of treating the underlying cause if one can be discovered. Incision of one or both corpora, with expression of blood clots, which form after a prolonged period, may be required.

Prognosis.—Impotence usually follows.

Tumors of the Penis

Benign.—

1. Condylomata acuminata (venereal warts) (see previous description)
2. Condylomata lata (syphilis) (see previous description)
3. Angioma
4. Balanitis xerotica obliterans, a weeping dermatitis of the glans penis, regarded as premalignant

Malignant.—

1. Carcinoma (squamous cell carcinoma)
2. Sarcoma—very rare
3. Multiple hemorrhagic sarcomas—very rare

Carcinoma of the Penis

Carcinoma of the penis is a relatively common malignant tumor. It is thought that accumulated smegma and uncleanness are predisposing factors. It is practically never found in the Jewish race or Mohammedans, both of whom practice circumcision as a religious rite in the first week of life. Strangely enough, if circumcision is performed on a child of 5 years, it does not prevent him from developing carcinoma in adult life, suggesting that whatever the carcinogenic factor may be, it remains latent throughout most of the life's span. Equally interesting is the fact that carcinoma of the cervix is relatively uncommon in Jewish women. The exact etiology of carcinoma of the penis is unknown.

Site.—The majority of carcinomas of the penis arise on the glans or in the coronal sulcus. The lesion may be papillary, cauliflower, or infiltrating in type. Any of these may ulcerate. Metastases to the inguinal nodes occur early in the disease. Secondary infection of the nodes results in suppuration and necrosis.

Diagnosis.—This is made on the clinical appearance and biopsy. Early diagnosis is important.

Treatment.—

1. Partial amputation of penis
2. Complete amputation of penis with radical excision of the inguinal lymph nodes
3. Caustic excision of the tumor, with implantation of radon seeds
4. Irradiation

CONDITIONS OF THE URETHRA

1. Urethritis (gonorrhea, nonspecific; Reiter's disease)
2. Stricture
3. Perurethral phlegmon (perurethral abscess)
4. Tumors
5. Rupture

Urethritis

Etiology.—*Gonorrheal urethritis* is an acute specific inflammatory process involving the anterior urethra and caused by the Neisserian organism (gram-negative diplococci). The inflammatory process is characterized by an exudation of phagocytes in an endeavor to limit the infection. The production of pus results in a profuse urethral discharge. The glands of Littre in the anterior urethra are involved; this explains why an inflammatory stricture is found only in the anterior urethra.

Earlier teaching stressed the importance of avoiding spread of the infection to the posterior urethra and to the prostate by urethral irrigations or instrumentation. With modern chemotherapy in which neither irrigations nor instrumentation are used, spread of the inflammatory process to the posterior urethra and the prostate appears to occur spontaneously in some cases within the first 24 hours.

Symptoms.—Symptoms of an acute gonorrheal urethritis are a profuse urethral discharge, frequency, burning, and urgency.

Diagnosis.—This is made on the history of exposure and the finding of gram-negative diplococci, either intracellular or extracellular or both, in smears of urethral discharge.

Complications of Gonorrheal Urethritis

1. Epididymitis (elevate the scrotum apply heat)
2. Prostatitis—acute, may become chronic
3. Prostatic abscess
4. Urethral stricture
5. Arthritis
6. Gonorrheal endocarditis—very rare

Treatment.—(In order of preference)

1. Penicillin—300,000 units daily for 2 days
2. Streptomycin—1 Gm daily for 2 days
3. Sulfonamides—either trisulfas or sulfadiazine, 4 Gm daily for 3 days, gradually decreasing

4. Irrigations—Protargol $\frac{1}{4}$ of 1%, potassium permanganate 1:12,000 solution, silver nitrate 1:10,000 solution—no longer used in acute or newly acquired infections but of considerable value in the chronic or recurrent form.

Nonspecific Urethritis (see page 891).

Reiter's disease is characterized by the triad (1) urethral discharge, (2) conjunctivitis, and (3) polyarthrititis.

Its cause is unknown. No specific organism has been recovered from the urethral discharge. *Conjunctivitis* may be severe and progresses to *eosion*. *Treatment* is not specific and must therefore be symptomatic and palliative. Recovery occurs after a period of months.

Stricture of the Urethra

Stricture of the anterior urethra is usually inflammatory but may be due to tearing of the urethra by a blow. Stricture of the posterior urethra is always traumatic in origin.

Diagnosis.—

- 1 History of a previous acute inflammation or trauma
- 2 History of a narrow urinary stream or forking of the stream
- 3 Signs of infection (frequency, urgency, burning, associated with a narrow stream)
- 4 Palpation of the urethra—an indurated area often palpable
- 5 Urethrogram—x-ray of the urethra taken at the time of injection of an opaque liquid or jelly, the narrowed area in the urethra visualized
- 6 Calibration of the urethra with a bougie-à-boule, determination of the site, length, and size of the stricture with this instrument

Treatment of Stricture—

- 1 Dilatation of the urethra. This may be carried out with filiforms and followers (gum elastic dilators attached to a fine guide), Philip's bougies, metal sounds (Laforte's), or by a Kollmann dilator.
- 2 Internal urethrotomy. A specially designed urethrotomy knife is passed down the urethra to the site of the stricture and a longitudinal incision of the stricture is made.
- 3 Surgical excision of the stricture. This is performed with end-to-end anastomosis or tube graft.

Instrumentation of Urethra

- 1 For urinary retention
- 2 For stricture of urethra

Any instrumentation of the urethra should be preceded and followed by a thorough irriga-

tion of the urethra with a mild antiseptic. Urethral chills with high fever due to toxic absorption are practically never seen if this precaution is taken. Sterile technique should be maintained throughout. Adequate lubrication is essential. Petroleum jelly, liquid lubricant, and olive oil instilled into the urethra are all satisfactory.

Technique of Instrumentation

Catheterization of the urinary bladder may be required for acute retention due to prostatism or following surgical operations. There are several different types of catheters with which this procedure may be carried out:

1. Soft rubber catheter, either plain or Foley bag type
2. Soft rubber catheter with catheter stylet
3. Coudé catheter (one angle on distal end)
4. Bicoudé catheter (two angles on distal portion)

Fig. 455—Foley bag catheter in the bladder.

In patients with postoperative retention of urine or retention due to prostatism, an attempt is first made to pass a soft rubber catheter. This may be either a plain catheter or one with

a distensible balloon on the end (Foley bag catheter) if it is desired to leave it in place as a retention catheter. The urethra is well irrigated, and the catheter lubricated (either with sterile liquid paraffin, glycerine, or olive oil or lubricating jelly). The catheter is then passed *gently*. This is successful in the majority of cases. Additional lubrication of the urethra by the injection of 5-10 ml. of the sterile lubricant into the urethra prior to passing the catheter often converts a difficult into an easy catheterization.

In cases of prostatism it may be impossible to pass a soft rubber catheter. A curved catheter stylet may be used to increase the rigidity of the catheter. The catheter with the stylet is guided into the bladder over the obstructing prostatic lobe.

If the above two maneuvers are not successful a *condé* or *bicondé* catheter is passed. These are gum elastic silk woven catheters with one bend about 1 cm. from the tip (*coudé*) or two bends—1 cm. from the tip and the other 7.5 cm. from the tip (*bicoudé*). They are most helpful in cases of prostatic obstruction.

For many years it has been taught that decompression of the bladder should be carried out very slowly and gradually over a 24-hour period, in order to avoid sudden massive hemorrhage. Sudden massive hemorrhage following rapid decompression is so rare that most urologists in the course of a lifetime have not seen a case.

A *bougie-à-boule* is an instrument about 25 cm. long, with a narrow shaft and an acorn-shaped enlargement at one end and an olive-shaped enlargement at the other end. The enlargements at the end are calibrated in size from Fr. No. 14 to Fr. No. 24. The instrument may be either gum elastic silk woven or metal. It is used to explore the urethra to determine the presence of a stricture. Its advantage over a sound is that tissue-paper-thin strictures can be palpated, whereas with a sound they would be broken down without being recognized. The largest size (Fr. No. 24) is passed first. If an obstruction is encountered, the instrument is withdrawn and the next size passed, continuing thus down the scale until one is found that can be passed to

the bladder. On withdrawing the bougie, the enlarged end is felt to grate and pass irregularly in the scar tissue of the stricture. It is thus possible to chart the site, length, and caliber of the stricture. Such information is valuable in subsequent treatment.

Metal Sounds.—The usual metal sound is an instrument that should be used with great delicacy and care. Under no circumstances should force be used. The urethra is irrigated and the instrument (Fr. No. 12 or 14) lubricated. The point is passed through the meatus, the handle of the instrument being held over the patient's abdomen. As the deep urethra is approached, the handle is rotated through an arc of approximately 120 degrees downward, the curved proximal end of the sound thus sliding under the symphysis into the bladder. The sound should be closely opposed to the roof of the urethra throughout its entire passage.

Koffmann's dilator is a metal instrument with expanding blades that are controlled by a screw arrangement at the head. It is passed like a sound. A scale also attached to the head of the instrument indicates the caliber obtained as the blades are opened. This dilator is seldom used.

Periurethral Abscess (Periurethral Phlegmon)

Periurethral abscess may occur at the site of any inflammatory stricture or upon the use of an indwelling urethral catheter for a prolonged period, causing erosion of the urethra.

Extravasated urine spreads into the scrotum, causing marked swelling of the scrotum and penis, and into the abdominal wall. It is limited in its spread by the attachment of Colles' fascia inferiorly to the lower border of the urogenital diaphragm and laterally to the rami of the ischium and pubis; superiorly it spreads within the abdominal wall deep to Scarpa's fascia.

The treatment of periurethral abscess and extravasation of urine consists of the following:

1. Diversion of the urinary stream by suprapubic cystostomy.
2. Incision and drainage of the abscess.
3. Multiple incisions with through-and-through drainage in the area of extravasation.

New Growths of the Urethra

New growths of the urethra, benign or malignant, are very rare; 192 cases of primary carcinoma of the male urethra have been reported.

Symptoms and Signs.—

1. Difficulty in micturition is the commonest symptom of growths in the anterior urethra.
2. Hematuria is the commonest symptom of growths in the posterior urethra.
3. The growth may be palpable.

The dysuria when associated with a perineal mass and difficulty in dilating a previously easily dilated stricture are suggestive of new growth.

Diagnosis.—This is made on the following

1. Symptoms
2. Palpation of the urethra
3. Endoscopic examination
4. Biopsy

Treatment.—

1. Amputation of the penis, the treatment of choice.
2. Extensive resection of the urethra.
3. Direct application of radium for a relatively small growth in the fossa navicularis.
4. Fulguration of small growth.

Prognosis.—Carcinoma of anterior urethra—50% of patients are living after 2 years. Carcinoma of posterior urethra—50% of patients are dead one year after operation, indicating the difficulty of complete removal of the growth if situated posteriorly.

Urethral caruncle is a growth resembling a thrombosed vein which appears in the female at the external urinary orifice. It is relatively common, benign, and treated by excision or fulguration.

Rupture of the Urethra

Rupture of the urethra is caused by direct violence (such as falling astride a beam) or by indirect violence (such as crushing injuries of the pelvis). The site of the rupture is commonly in the membranous or prostatic urethra.

Signs of Rupture.—

1. Bleeding from the external urinary meatus.
2. Hematoma at the site of injury.

3. Inability to void.

4. Variable degrees of shock.

Treatment.—Depending upon the conditions present at the examination, one of several methods may be used to treat the ruptured urethra.

1. If a soft rubber urethral catheter can be passed, it should be left in place and taped in.

2. Immediate suprapubic cystostomy with repair of the urethra. The bladder is opened suprapubically, and a sound is then passed through the bladder and internal sphincter into the urethra to the site of rupture. Another sound is passed through the external meatus into the urethra until it meets the former (male and female sounds). The sound passed from the bladder side is used to direct the other sound into the bladder. When this has been achieved, a catheter is attached to the sound passed through the penis, and the sound and catheter are withdrawn in a retrograde manner. The catheter is left in situ as a splint for the urethra. A de Pezzer tube is inserted into the bladder and brought out through the suprapubic incision.

3. Immediate repair by exposing the site of rupture in the perineum, identification of the torn ends of the urethra, and end-to-end anastomosis of the ends over a rubber or Foley bag catheter.

4. Suprapubic cystostomy only, with repair of the urethra at a later date.

5. Perineal section and urethrotomy. A catheter is passed through the urethrotomy opening to the bladder to divert the urine. The urethra is repaired at a later date.

6. In the late cases, or in cases of old injury or those previously treated by suprapubic cystostomy, the scarred torn urethra is exposed in the perineum. The scar is excised, and a split-thickness skin graft is built up over a tracheal cuff placed on a Foley bag indwelling catheter. The cuff with its attached skin graft is then positioned on the catheter to fill the gap caused by the excision of the scar. Two inches or more of the urethra can be replaced by this method.

All cases of rupture of the urethra will require periodic dilatation throughout the remainder of life.

SCROTUM AND SCROTAL CONTENTS

Congenital Anomalies

Anorchidism—congenital absence of both testes

Monorchidism—development of only one testicle.

Synorchidism—the fusion of both testicles intra-abdominally; has only been discovered at operation or autopsy.

Polyorchidism—supernumerary testicles.

Cryptorchidism—congenital malposition of the testicle

The congenital anomalies with the exception of cryptorchidism are rare

Surgical Conditions of the Scrotum

Injuries.—The scrotum may be subjected to a direct blow, lacerating wound, or avulsion. A laceration is thoroughly cleaned with soap and water, débrided, and sutured. *Avulsion of the entire skin of the scrotum* may occur in industrial accidents, where wheels and belts are employed. The immediate treatment required is that for shock, followed by covering the scrotum with skin flaps.

Inflammation.—Inflammation of the scrotal wall usually occurs secondary to general diseases such as diabetes, cardiovascular failure, etc. It may also occur as the result of a perirethral phlegmon, extravasation of urine, and chemical or physical trauma (e.g., frostbite).

Tumors.—Tumors of the scrotum are very rare. The treatment is excision.

Elephantiasis.—This condition, in which there may be enormous swelling of the scrotum, is due to infestation by filariae which fill the lymphatic channels, causing obstruction. The disease is rare in temperate, but common in tropical, climates. The enlarged scrotum may reach the knees. Treatment consists of excision of the burdensome excess tissue.

Surgical Conditions of the Scrotal Contents

Vestigial Structures in the Scrotum

Appendix testis (i.e., hydatid of Morgagni) is pedunculated and attached to the front of the head of the epididymis or lies in the groove between the testis and epididymis.

Appendix epididymis is a pedunculated hydatid. It is rare. It is attached to the front of the upper pole of the epididymis.

Paradidymis or *organ of Giralès* is a collection of small tubules found above the head of the epididymis and in the lower end of the spermatic cord in front of the vessels.

Vasa aberrantia or *ductuli aberrantes* are coiled canals with blind ends in the epididymis. The inferior (that of Haller) is the larger and is located in the tail of the epididymis.

Testicular Tunics

Hydrocele.—A hydrocele is a sac of fluid within the scrotum, surrounding the testicle, the sac being formed by the tunica vaginalis. This is the commonest type and is called *idiopathic vaginal hydrocele*. In *congenital hydrocele*, the processus vaginalis communicates with the abdominal cavity. Elevation of the scrotum causes the fluid to return to the peritoneal cavity. In *infantile hydrocele* the tunica vaginalis extends up to the internal inguinal ring. The sac, however, has no connection with the peritoneal cavity. *Encysted hydrocele of the cord* is associated with the spermatic cord. The processus vaginalis is closed above and below, so that the sac moves with the cord when traction is applied to the testicle. A *secondary hydrocele* may occur as a complication of epididymo-orchitis, either acute or chronic.

Symptoms.—The patient notices a gradually increasing painless swelling in the scrotum.

Diagnosis.—This is made on the presence of a scrotal mass and by transillumination. The spermatic cord and the external inguinal rings are normal to palpation and do not suggest an inflammatory process. In a hematocoele, light is not transmitted. An epididymis is tender to palpation.

Treatment.

1. **Aspiration** by means of a large-caliber needle. This procedure must be repeated at intervals. It is not curative; the hydrocele recurs and the sac gets thicker.

2. **Injection**. A needle is inserted into the sac and the fluid is withdrawn. Quinine and urea hydrochloride solution at intervals of one

week is injected into the sac on two or three occasions. Some claim permanent cure by this treatment.

3. **Excision of the hydrocele.** The sac is opened, everted, and the excess wall is excised. The edges are sutured behind the epididymis.

4. **Scrotal support.** This often provides comfort.

Hematocoele.—This is a collection of blood in the tunica vaginalis. It usually results from an injury. A common cause is the aspiration of a hydrocele. Repeated hemorrhages may occur, giving gradual enlargement. The testicle is flattened by pressure. Treatment consists of opening the sac, removing the clot, and excising the sac.

Chylocele.—Chylocele is the presence of chyle fluid (lymphatic fluid which contains cholesterol particles from the digestive tract) in the tunica vaginalis. It is rare but may occur in cases of chronic lymphatic obstruction, e.g., filariasis.

Hernia.—A hernia containing intestine may be present in the scrotum, as well as a hydrocele. It is one of the more important conditions to be differentiated from hydrocele. It does not transilluminate.

Epididymis

Injuries to the epididymis are rare but may follow a direct blow. Swelling and edema occur.

Spermatocele and Cysts.—Cysts of the epididymis, particularly the head, are much more common than spermatocele. They are usually multiple and filled with a clear fluid. A spermatocele is a unilocular retention cyst derived from some portion of the sperm-conducting system of the epididymis. It is therefore filled with cloudy fluid. Treatment is excision (of the cyst or spermatocele).

Inflammation.

GONORRHEA.—Acute gonorrheal epididymitis occurs as a complication of gonorrheal urethritis. The epididymis becomes enlarged, hard, and exquisitely tender. Pain is acute. Fever of 103°-104° F is often present. When epididymitis is acute, urethral discharge is scanty.

Diagnosis.—The diagnosis of epididymitis is determined by the following:

1. History of exposure
2. An enlarged tender mass found on physical examination
3. High fever
4. The finding of Neisserian organisms in the urethral discharge

Differential Diagnosis.—Epididymitis must be differentiated from torsion of the testicle. Prehn has described a useful sign in this connection, namely, that elevation of the scrotum gives relief of pain in epididymitis but increases the pain in torsion of the testicle (Prehn's sign).

Treatment—

1. Specific—penicillin or streptomycin
2. Local—elevate the scrotum (adhesive bag)
3. Application of hot compresses or ice packs—either works satisfactorily, although heat gives more relief from the pain.

Acute epididymitis is usually followed by resolution, provided it is not tuberculous in origin.

NONSPECIFIC EPIDIDYMITIS.—This lesion may occur without determinable cause, presumably due to lowered tissue resistance. The epididymis becomes enlarged, hard, and tender. There is no urethral discharge, and frequently no history of exposure.

Treatment—

1. Administration of penicillin or streptomycin—either will reduce the fever but will not alter the eventual course of the disease.
2. Elevation of the scrotum and applications of heat or cold.
3. Incision and drainage of the testicle (If the epididymis is incised, pus is nearly always found and varies in amount from a few drops to a half ounce. Incision and drainage usually give prompt relief of pain but do not otherwise influence the course of the disease. The acute infection may progress to abscess formation requiring drainage. Sterility of the affected testicle usually follows an epididymitis, probably due to obstruction.)

TUBERCULOUS EPIDIDYMITIS.—(See page 878.)

SYPHILITIC EPIDIDYMITIS.—Very rare—(syphilitic orchitis in the latent stage of the disease is not uncommon).

Vas

Injuries to the vas are uncommon. The vas may be severed or damaged in hernia operations, most commonly in children. Inflammations of the vas, either gonorrheal, nonspecific, or tuberculous, are more common and cause pain in the inguinal region. With the exception of tuberculosis, they tend to subside when the associated epididymitis present resolves under treatment. On rare occasions localized abscesses form and require drainage. Beading of the vas on palpation is a sign of previous inflammation.

Vessels

Injuries of the Vessels.—Injuries are uncommon, with the exception of injury to a varicocele, which may cause rupture of some of the vessels. Extravasation of blood into the scrotum occurs. This tends to be absorbed if the patient is placed at rest.

Varicocele.—A varicocele is that condition in which the veins of the pampiniform plexus have become varicose. The extent varies. It is usually associated with a lax pendulous scrotum. It is relatively common on the left side in young men, very rare on the right side, and occasionally bilateral. It is described as "a bag of worms" because of the appearance on the surface of the scrotum. In older men it may be due to venous obstruction caused by the pressure of a renal tumor.

There are several theories as to its cause, none of which is entirely satisfactory. The two most common reasons given are (1) incompetence of the valves in the left spermatic vein and (2) the greater intravenous pressure in the left spermatic vein. The stagnation of blood may result in partial atrophy of the testicle.

Signs and Symptoms—

1. Varicocele may be asymptomatic, or the patient may complain of pain in the testicle. In a great many cases there is a psychoneurotic element, as the patient is conscious of an inferiority rather than pain.

2. When the patient stands, the vessels of the pampiniform plexus become distended and readily palpable. On recumbency with elevation of the scrotum, the vessels empty

Treatment.—

1. Support the scrotum with a suspensory belt. Cold baths are sometimes helpful.
2. Operation in selected cases. The majority of the veins are isolated from the vas, making certain to leave the artery of the vas and a few veins behind. The main group is divided and a 4 cm. length excised. Each end is tied with a transfixing ligature and then approximated by tying the ligatures together.

Testicle

Contusions.—Blows to the testicle are fairly common. The majority of such injuries are fortunately slight. Severe trauma will cause ecchymosis of the scrotum, acute pain, swelling of the testicle, and exquisite tenderness. When the acute episode subsides, atrophy may follow.

Treatment includes bed rest, elevation of the scrotum, and ice bags to the scrotum.

Wounds of the Testicle.—Stabbing wounds of the testicle are uncommon. Extensive lacerations of the scrotum, with partial or complete loss of glandular tissue, are more common in the accidents of industries and modern warfare. After treating shock, the area is thoroughly cleansed with green soap and water, debrided, and every effort made to preserve as much of the testicle as possible. Usually very little tissue can be saved as the tunica albuginea is extensively torn and the seminiferous tubules bulge through the rent.

Inflammations.—

Acute orchitis.—Acute orchitis, nonspecific, may occur, as a rare complication of any generalized infection. It is characterized by a sharp rise of temperature, chills, headache, pronounced weakness, leukocytosis, pain, and swelling of the testicle. The epididymis and spermatic cord may be involved.

Treatment consists of elevation of the scrotum and the application of heat. Incision and drainage may be required later and occasionally orchectomy. Even if drainage is not required, testicular atrophy usually ensues.

Orchitis of Mumps.—Acute orchitis occurs as a complication of mumps in 20% of cases. The incidence in infants is much less. Testicular atrophy follows in over half the cases. It has been claimed by some that the atro-

is due to an acute inflammatory hydrocele, and that if this is drained during the acute stage, atrophy of the testicle will not ensue. These claims, however, do not appear to be true, as testicular biopsy clearly shows that an acute inflammatory reaction occurs within the substance of the testicle, which explains the subsequent atrophy.

Chronic Orchitis—(1) Tuberculous and (2) syphilitic

Clinically, syphilitic infections of the testicle are rare. Yet at autopsy, syphilitic fibrosis of the body of the testicle is so common that it can be said that syphilis attacks the testicle in preference to any other tissue, with the possible exception of the heart and aorta.

Latent syphilitic orchitis occurs frequently and often passes unnoticed.

Congenital syphilitic orchitis develops from the 3rd-10th month of life and results in diffuse fibrosis and atrophy (of the testicle).

Gumma of testis is a late manifestation of syphilis.

Neuralgia of Testicle—The complaint of pain in the testicle, usually intermittent, gnawing in character, and frequently severe, is most difficult to treat. It may be caused by involvement of the genitofemoral nerve in scar tissue, hernia, prostatitis, a localized healed lesion in the testicle, or low ureteral stone.

Torsion of the Testicle—Torsion of the testicle is, in fact, rotation or torsion of the spermatic cord, which shuts off the blood supply to the testicle. Torsion can occur only if the epididymis is not attached to the posterior scrotal wall and if there is a complete and high investment of the testis and epididymis by the tunica vaginalis. If the tunica vaginalis is attached high to the cord, contraction of the cremasteric muscle with its spiral fibers may cause complete rotation of the testicle, shutting off the blood supply. The torsion is usually anticlockwise and nearly always intravaginal. The etiology is unknown.

Symptoms and Signs—

1. Sudden acute onset of pain in the testicle, which may be agonizing.
2. Elevation of the testicle in the scrotum.
3. Prehn's sign—elevation of the scrotum accentuating the pain.

1. If of long duration, swelling of the scrotum with redness of the overlying skin; also some elevation of temperature.

Treatment—

1. If soon after onset—try to reduce the torsion manually, by twisting the supported testis from within outward. If this increases the pain, twist it in the opposite direction.

2. Up to 24 hours after onset—expose the testicle through an inguinal incision, untwist it, return it to the scrotum, and suture it there.

3. If the torsion has existed longer than 24 hours, the testis will appear blue-black and lifeless, in which case it should be removed.

Cryptorchidism—Cryptorchidism is congenital malposition of the testicle. It may be the following:

1. Abdominal (nondescent)
2. Inguinal (partial descent)
3. Retention of the testicle in the upper part of the scrotum
4. Perineal
5. Penile

Most cases encountered clinically are in the inguinal region and due to incomplete descent. They are underdeveloped and are frequently subjected to repeated trauma. For years it has been claimed that the incidence of malignancy in an undescended testicle is exceedingly high as compared to a normally descended testicle. Recent work would indicate that this is not true and that the incidence of malignancy is no higher than in a normally descended testis. Atrophy of the testicle with aspermatogenesis is a frequent finding.

TREATMENT FOR INCOMPLETE DESCENT OF THE TESTICLE (CRYPTORCHIDISM)—The ideal age for treatment is up to 9-11 years.

1. *Hormonal*: In some children the testes are either high in the scrotum or in the inguinal canal. In some of these, the injection of 500 units of anterior pituitary-like substance (A.P.L.) daily for 20 doses, followed by a rest period of 10 days, and then another series of 10 injections will cause the testes to descend. In many cases, however, the testicle is bound down to the surrounding tissue by adhesions. In these, A.P.L. will not cause the testicle to descend.

In practice, it is customary to give a course of A.P.L. prior to proceeding with surgery. If the testicle does not descend and surgery is

required, it is found that the tissues are more pliable after a course of A.P.I. and the testicle has an increased blood supply.

2. *Surgical*: If hormonal therapy fails to bring the testicle down into the scrotum, the inguinal canal should be opened, the cord and testicle found, and the congenital hernia repaired. The cord can then be lengthened sufficiently to allow positioning of the testicle in the new bed made for it in the scrotum.

Tumors of the Testicle.—The views held regarding tumors of the testicle have altered considerably during the past 30 years. In 1929 Zondek discovered prolan A in the urine of a patient suffering from teratoma testis. Soon it became common practice to regard the quantitative amount of prolan A found in the urine as an index to the type of tumor present and the prognosis. Opinion has now shifted so that it may be said that, whereas a positive prolan A in the urine indicates the presence of a testicular tumor, a negative prolan A does not exclude a tumor. In chorionepithelioma there is a very high excretion of prolan A.

Classification—

<i>Tumors of the Testicle</i>	<i>Incidence</i>
1 Seminoma (germinoma)	35%
2 Teratoma	42%
3 Embryonal carcinoma (including chorionepithelioma)	23%

Incidence—Tumors of the testicle are uncommon but occur with sufficient frequency to be important. They form approximately 20% of all tumors in the male, and are commonest from 20-40 years of age. Testicular neoplasms may be found at any age, even in the newborn, and most clinicians and pathologists agree that they are all malignant or potentially so.

Seminoma (Synonyms; *germinoma*; or *embryonal carcinoma with lymphoid stroma*)—One third of all testicular tumors are monocellular seminomas made up of rounded polyhedral elements with sharp cell borders. The cytoplasm is often clear. The cells are usually arranged in unorganized masses of cords divided by trabeculae of connective tissue. Variations in structure may occur. The lymphocytic infiltration of the connective tissue trabeculae in seminomas has led some clinics to use the term *embryonal carcinoma*, with

lymphoid stroma. This is considered to be a misleading term. Foci of necrosis are often encountered. Invasion of the adnexae and cord is exceptional, although in embryonal carcinomas it is the rule.

The resemblance between seminoma cells and some cells of the seminiferous tubules is taken as evidence that seminomas arise from spermatogonia cells of the seminiferous tubules.

Teratoma—There is a great range of variation in the structure of teratomas. Some of the more appalling facts about tumors of the testicle are that (1) 42% are either misdiagnosed or undiagnosed prior to admission (Schwartz and Mallis), (2) an average of 7.5 months elapses from the time when the patient first seeks medical attention to the time that he is referred for surgery (Schwartz and Mallis), and (3) 43% have metastases at the time of admission (Lewis). They are characterized by the presence of epithelial masses, glands, and cysts. Many of these structures are organized in combination with undifferentiated or specialized mesenchymal tissues such as cartilage. Transitions occur and the resulting picture is one of mixed figures in which some semblance of organization can often be discerned. Squamous cell nests and cysts, often keratinizing, are frequent; glandular appendages and adult hair are rare. Epidermoid cysts outnumber dermoid cysts 10:1.

Embryonal Carcinoma—Tumors of this type, which include embryonal adenocarcinoma and papillary adenocarcinoma, are often confused with seminomas, although they differ not only in fundamental cell type but in biologic behavior and prognosis as well. They show considerable variation in cell type, e.g., epithelial cells, cuboidal cells, columnar cells, and papillary structures. The cell type is of no known biologic significance and does not determine the prognosis.

Chorionepithelioma—These tumors may be suspected grossly because they are strikingly hemorrhagic. In addition they produce a very high excretion of prolan A in the urine (100,000 or more mouse units/liter).

Microscopically they are easily recognized because of their characteristic appearance. They have two cellular components arranged so as to duplicate the architecture of the placental

illi. The combination of compactly grouped cytotrophoblastic cells and giant multinucleated syncytial structures, arranged at the borders of the cellular masses, makes one of the most striking microscopic pictures in all pathology.

Signs and Symptoms of Tumor of the Testicle.—Tumor of the testicle may occur at any age, but 80% occur from 20-40 years of age. There are two cardinal symptoms:

1. A painless swelling in the testicle.
2. Sense of weight in the scrotum. Attention is often drawn to the testicle by some insignificant trauma, or the patient may have noticed a gradual enlargement to which at first he paid little attention.
3. The first symptom noted may be the result of metastases or of lymphatic involvement, e.g., loss of weight, abdominal pain, pain in the back or spine, or a slight cough.
4. On palpation, the testicle is usually smooth and regular in early cases but nodular and cystic in later cases. The skin is red and shiny from stretching, the surface blood vessels are dilated, and at a very late stage, ulceration through the scrotum may occur.
5. The presence of prolan A in the urine, i.e., a positive Aschheim-Zondek test, is indicative of tumor being present in the testicle, but a negative test does not exclude tumor.

Differential Diagnosis.—

1. Tumor
2. Hydrocele (often present with tumor)
3. Hematocele
4. Tuberculosis
5. Syphilis

All testicular swellings must be regarded as malignant until proved otherwise.

Metastases.—Metastases occur via the lymphatics to the deep abdominal and aortic nodes and via the blood stream to give widespread distal metastases. The lungs are most commonly involved. Blood stream invasion may occur early.

Prognosis.—The prognosis in testicular tumors is very poor. There is a 1-5-year cure in many cases of seminoma. So far, there has been no case of chorionepithelioma known to be cured. Taking all groups together, 40% are dead 2 years after surgery. The 5-year survival of all groups is 20%. The prognosis depends in part upon (1) the extent and rapidity with which the tumor grows and metastasizes and (2) the radiosensitivity of the tumor, e.g., abdominal metastases sometimes appear to melt away (temporarily) following radiation of the abdomen.

Treatment.—In the treatment of testicular tumor, one of several courses may be pursued as follows:

1. Simple orchiectomy
2. Orchiectomy and irradiation
3. Radical operation with removal of the regional and retroperitoneal lymph nodes on the affected side, followed by deep x-ray irradiation
4. Irradiation alone
5. Bilateral orchiectomy

Chapter 32

Diagnosis of Acute Abdominal Conditions

James R. McCorrison, M.D.

An acute abdominal condition is one in which the patient is rendered acutely ill and prompt treatment is urgently required. An early and accurate diagnosis is therefore most important in order that appropriate therapy may be instituted before the situation becomes worse. In many instances immediate or early surgical intervention is necessary, but, in others, conservative forms of therapy are required and operative procedures definitely contraindicated.

Several fundamental principles should govern the method of diagnosis of an acute abdominal condition. There is the necessity of making a serious and thorough attempt at an early diagnosis, which is based on the following:

1. A careful and complete history of the present illness and of events in the past that might conceivably have some bearing on the present situation

2. A painstaking examination

3. The application of a thorough knowledge of anatomy and physiology

4. The possession of a broad concept of the various diagnostic possibilities; errors of diagnosis more often made through failure to consider possibilities than from lack of ability to distinguish among various clinical entities under consideration

5. The exclusion of nonsurgical conditions

HISTORY

The history of the present illness must include a detailed account by the patient, rela-

tives, or friends who know the facts of its onset and the development of symptoms. This should always be supplemented by the history of previous illnesses and the state of health of the patient.

SYMPTOMS EXPERIENCED BY THE PATIENT

Pain.—Abdominal pain is one of the most common symptoms which calls for speedy diagnosis and treatment (Cope). Pain is present in almost every case of acute abdominal disease, and often it is of such severity that the indication for surgical treatment is immediately apparent. However, when the symptoms are indefinite, the temptation to temporize must be resisted and a conscientious attempt made to arrive at the diagnosis when the patient is first seen. By making such an attempt, dangerous carelessness will be avoided, and a correct diagnosis will lead to correct treatment. Narcotic agents (e.g., morphine) should not be given until the diagnosis is clear, because they mask symptoms and signs of severe, progressive intra-abdominal disease, which may require immediate surgical treatment. Cope has laid down the rule that the majority of severe abdominal pains which occur in patients who have previously been fairly well, and which last as long as 6 hours, are caused by conditions of surgical import. The earlier the diagnosis and treatment, the higher is the recovery rate from acute abdominal disease.

Diagnosis of Acute Abdominal Conditions

James R. McCorriston, M.D.

An acute abdominal condition is one in which the patient is rendered acutely ill and prompt treatment is urgently required. An early and accurate diagnosis is therefore most important in order that appropriate therapy may be instituted before the situation becomes worse. In many instances immediate or early surgical intervention is necessary, but, in others, conservative forms of therapy are required and operative procedures definitely contraindicated.

Several fundamental principles should govern the method of diagnosis of an acute abdominal condition. There is the necessity of making a serious and thorough attempt at an early diagnosis, which is based on the following.

1. A careful and complete history of the present illness and of events in the past that might conceivably have some bearing on the present situation
2. A painstaking examination
3. The application of a thorough knowledge of anatomy and physiology
4. The possession of a broad concept of the various diagnostic possibilities; errors of diagnosis more often made through failure to consider possibilities than from lack of ability to distinguish among various clinical entities under consideration
5. The exclusion of nonsurgical conditions

HISTORY

The history of the present illness must include a detailed account by the patient, rela-

tives, or friends who know the facts of its onset and the development of symptoms. This should always be supplemented by the history of previous illnesses and the state of health of the patient.

SYMPTOMS EXPERIENCED BY THE PATIENT

Pain.—Abdominal pain is one of the most common symptoms which calls for speedy diagnosis and treatment (Cope). Pain is present in almost every case of acute abdominal disease, and often it is of such severity that the indication for surgical treatment is immediately apparent. However, when the symptoms are indefinite, the temptation to temporize must be resisted and a conscientious attempt made to arrive at the diagnosis when the patient is first seen. By making such an attempt, dangerous carelessness will be avoided, and a correct diagnosis will lead to correct treatment. Narcotic agents (e.g., morphine) should not be given until the diagnosis is clear, because they mask symptoms and signs of severe, progressive intra-abdominal disease, which may require immediate surgical treatment. Cope has laid down the rule that the majority of severe abdominal pains which occur in patients who have previously been fairly well, and which last as long as 6 hours, are caused by conditions of surgical import. The earlier the diagnosis and treatment, the higher is the recovery rate from acute abdominal disease.

Information as to the character of the pain is helpful. Gripping pain is characteristic of intestinal obstruction, whereas an intra-abdominal abscess, such as a pelvic abscess, produces acute throbbing pain. Alteration of pain by respiratory movements is significant. The pain of pleurisy is made worse during inspiration and is diminished or abolished by temporary

frequently after unusual physical activity. It is necessary to know the time of onset of symptoms in estimating the probable extent of pathologic changes that have taken place.

The location sequence of pain is illustrated by typical acute appendicitis in which vague upper abdominal distress is first noticed, then periumbilical pain, and, finally, right lower quadrant pain. Another example is renal pain beginning in the costovertebral angle and referred to the external genitalia.

The patient is usually able to indicate the point of maximum pain. Examples of situations in which this is of diagnostic importance include local pain of strangulated hernia and mid-epigastric pain of pancreatitis.

Fig. 436—Location sequence of the pain of acute appendicitis

Fig. 437—Location sequence of renal pain

cessation of breathing. In most cases, pain of peritonitis is accentuated by deep inspiration, coughing, or movement.

The time sequence of symptoms is sometimes diagnostic, e.g., pain of peptic ulcer before and after meals, upper abdominal pain of gall bladder disease after a fatty meal and

Fig. 438—Mass of incarcerated femoral hernia a point of maximum pain and tenderness

Vomiting.—In acute abdominal disease vomiting is a common symptom of importance. Vomiting begins shortly after the pain, when there is sudden severe stimulation of the peritoneum or mesentery (e.g., perforated ulcer, high small bowel obstruction), but it may begin much later than the pain in other instances (e.g., large bowel obstruction). Vomiting is usually more frequent when the condition is acute but infrequent or absent when subacute. Nausea or loss of appetite as an initial symptom is often just as significant as vomiting (e.g., in acute appendicitis). The character of the vomitus should always be noted. When vomiting commences, the vomitus consists of stomach contents, but later it con-

tains yellow bile. When the vomitus changes to a dark green or black color, or later to a feculent type, paralytic ileus or intestinal obstruction is likely to be present.

Bowel Function.—Information concerning the presence of *constipation*, *diarrhea*, or *change of bowel habit* may be very useful. The nature of the stool and whether or not it contains blood, pus, or mucus are often significant (e.g., carcinoma of colon, diverticulitis).

Menstrual History.—Knowledge of the menstrual history is essential when trying to diagnose an acute abdominal condition in a female. Amenorrhea or an unusual type of menstrual period may indicate the likelihood

Fig. 459.—Local hypogastric distention owing to distended urinary bladder (dullness on percussion)

of pregnancy if the patient is of childbearing age

Urinary Function.—The history of urinary function is very important. Inability to pass urine or frequent voiding of small amounts is characteristic of urinary retention. Frequency of urination and dysuria are usually present when there is inflammation in or near some part of the urinary tract.

Age.—The age of the patient is of considerable diagnostic significance. Acute appendicitis may occur at any age, acute intussusception is commonly found in children under the age of 2 years, and acute obstruction of the colon due to carcinoma is uncommon in children and young adults

PHYSICAL EXAMINATION

A general physical examination of the patient should always be carried out. The examination should begin with *inspection*. The attitude in bed, facial expression, perspiration, respiratory movements, bodily movements, skin color, degree of tenseness, and other general characteristics are noted. Movement of the alae nasi and rapid breathing direct attention to the possibility of respiratory disease, extreme pallor associated with gasping respirations is suggestive of massive hemorrhage, and cold, clammy face and extremities indicate the imminence or presence of oligemic shock. Peritonitis causes the patient to remain immobile in order to avoid accentuation of pain, whereas the severe colics lead to restlessness.

The *pulse* is often unaltered early in acute abdominal conditions but will be weak and rapid if shock is present. The pulse rate is nearly always increased when hemorrhage or peritonitis is advanced. The pulse cannot be relied upon as a guide in the early stages of acute abdominal disease.

The *body temperature* may be subnormal, normal, or elevated. During a phase of shock it is likely to be quite low. In acute appendicitis or cholecystitis the temperature may be normal or elevated, but it often falls sharply if perforation of the viscus occurs. When the temperature is very high the chest or urinary tract should be suspected as a site of infection. Rigors or chills are frequent when fever is present in urinary tract infections

Inspection of the tongue is often helpful, as the tongue is usually coated or furred in acute abdominal conditions. In addition, the breath may be foul, particularly in intestinal obstruction.

The head and neck, eyes, ears, nose, throat, chest, and cardiovascular system should be examined, followed by the spinal column and nervous system.

Abdominal Examination.—Finally, a careful examination of the abdomen is performed. *Inspection* is very important and, with appropriate lighting, abnormal local or general distention, the presence of a large mass or external hernia, visible peristalsis, degree of mobility of the abdominal wall, and discoloration of the skin may be appreciated

Hyperesthesia is sought for by pin stroke or pinch. The point of the pin is drawn downward in vertical strokes over the anterior abdominal wall and loins. Hyperesthesia may appear in the distribution of peripheral nerves, whose branches are irritated by an inflammatory process, or it may appear in the segmental distribution of that part of the spinal cord which innervates the affected viscus. In acute appendicitis, hyperesthesia is frequently demonstrable over the abdominal distribution of the right 10th and 11th thoracic nerves.

The examiner, after making certain that his hand is warm, should begin *palpation* of the abdomen at a site distant from the point of maximum pain indicated by the patient. The hand should be applied with the palm flat on the skin and gentle pressure exerted with the pulps of the fingers. By this means the texture and temperature of the skin may be determined, muscular rigidity or contraction

appreciated, areas of tenderness located, masses felt, and movements of organs or abdominal masses with respiration detected. Contralateral tenderness on deep palpation of one side of the abdomen is often present in acute intra-abdominal disease but is absent in intrathoracic disease. If the patient flexes his hips, the abdominal wall will be more relaxed and the examination more satisfactory.

Muscular rigidity may be marked in conditions which cause severe irritation of the parietal peritoneum, as is the case in perforated peptic ulcer or traumatic rupture of a viscus. It is important to realize that rigidity may be minimal or absent in these acute conditions when the abdominal muscles are weak or flabby, when the patient is very ill due to toxemia, and when the patient is elderly or debilitated. It is a well-known fact that many aged patients exhibit much less pronounced symptoms and signs of acute abdominal disease than do younger adults and children. In oligemic shock with marked hypotension, rigidity may be reduced or completely obliterated despite the presence of severe peritoneal irritation. Simultaneous palpation of both rectus muscles is of value in assessing the character and degree of spasm. Unilateral rectus spasm may appear reflexly during renal colic but not in peritonitis, because there is nothing to limit the spread of irritating intraperitoneal fluid to one side. The loins are best palpated by the use of both hands, by which means masses and muscular rigidity are readily detected. Palpation of the abdomen after administration of a preoperative narcotic agent or after induction of anesthesia prior to laparotomy may make possible the detection of a

Fig. 120. Distribution of the 10th and 11th thoracic nerves in acute appendicitis.

mass not previously felt because of intense muscle spasm

All hernial orifices must be scrupulously palpated, for hernias may be small and easily overlooked. Palpation of the femoral pulsations must be carried out, as one or both are absent in aortic or iliac arterial occlusion. When there is acute inflammation in relation to the psoas muscle, psoas rigidity is usually produced with flexion of the corresponding hip.

Percussion of the abdomen is of value in outlining the contour of the liver and spleen, in demonstrating free gas in the peritoneal cavity (especially if it obliterates liver dullness), and in outlining areas of resonance over gas-filled bowel or dullness over solid masses.

Rebound pain is elicited by pressing deeply on the side of the abdomen away from a suspected inflammatory lesion and then quickly releasing the pressure. As the abdominal wall springs out to its original position, sudden pain is felt at the site of pressure or at the site of the inflammatory lesion.

Accentuation or relief of pain on change of position is often of significance. An example of this phenomenon is increase of pain and nausea on change from the supine to the sitting position when volvulus of bowel is present. This condition is due to increased tension on the inflamed and stretched mesentery.

Careful and prolonged *auscultation* of the abdomen should never be omitted. Peristalsis may be increased, diminished, or absent in the presence of an acute abdominal condition. Peristalsis is absent if no sounds are heard over a period of several minutes, a condition that indicates the presence of paralytic ileus owing to diffuse peritoneal irritation. There are two common forms of increased peristalsis. Constant loud borborygmi of varying intensity but no definite pattern occur in acute gastroenteritis. This type of peristalsis has no definite rhythm, and its intensity wanes without corresponding change in the associated abdominal discomfort. In acute mechanical bowel obstruction, abnormal sounds are produced by the rhythmic contractions of the intestines. Borborygmi of gradually increasing

intensity occur, which rise to a crescendo and then abate until only scattered tinkling sounds may be heard. The patient complains of cramps which come and go with the peristaltic activity. In chronic partial obstruction of the distal small bowel and during recovery from peritonitis, hollow gurgling and tinkling sounds are produced in the dilated, partially fluid-filled loops of bowel undergoing periodic contractions. These sounds are not rhythmic and may or may not be accompanied by abdominal cramps. Occasionally friction sounds are heard in peritonitis, and the transmission of cardiac and respiratory sounds through the abdomen occurs in the presence of intestinal distention and peritoneal exudate.

Rectal examination (with or without anoscopic and sigmoidoscopic examination) must never be omitted because it affords considerable information concerning the pelvic cavity. In males, anterior palpation will reveal abnormalities of the prostate or seminal vesicles, as well as fullness of the bladder. In females, anterior rectal palpation reveals abnormalities of the uterus and swellings in the pouch of Douglas. In both males and females high anterior palpation will reveal tenderness of the pelvic peritoneum.

High palpation along the rectal canal will reveal the presence of rectal lesions, impaction of feces, and foreign bodies. Lateral palpation may reveal a mass or elicit tenderness. Posteriorly, any mass or tenderness in the hollow of the sacrum or in the region of the sciatic foramina can be palpated.

After the gloved finger is withdrawn, it can be inspected for the presence of blood, pus, or mucus. Feces or other material present may be smeared on a piece of filter paper for the chemical detection of occult blood. Bimanual rectoabdominal examination is particularly valuable and in children permits exploration of the lower abdominal cavity as well as the pelvis.

In adult females, *vaginoabdominal* examination may elicit additional information. This is particularly valuable in examination of the female pelvic organs as it permits accurate evaluation of the size, shape, position, mobility, and tenderness of pelvic organs, tumors and masses (see Chapter 28, Female Genital Tract).

SPECIFIC TESTS AND SIGNS

The *shake test* is frequently of great value when the patient has difficulty identifying the point of maximum abdominal pain. To perform the test, the patient's pelvis is shaken transversely as he lies relaxed in the supine position. When the parietal peritoneum is irritated, this maneuver will cause pain and will enable the patient to indicate its exact location. A vigorous cough by the patient may yield the same information.

Fist percussion over the lower anterior thoracic wall causes acute pain in acute upper abdominal conditions (e.g., acute hepatitis, acute cholecystitis). It is performed by placing one hand flat on the skin and percussing it with the fist. Renal and spinal pain may also be revealed in this way.

The *psaos test* is performed by having the patient forcefully flex his thigh against the pressure of the examiner's hand. Pain is then experienced when there is an inflammatory lesion in contact with the psoas or iliacus muscle. Lesser degrees of psoas spasm may be demonstrated by the production of pain and resistance when the examiner hyperextends the patient's hip (e.g., in acute appendicitis).

The *obturator test* is useful in confirming the presence of an inflammatory lesion adjacent to the obturator internus muscle. When it is positive, medial rotation of the flexed thigh will produce hypogastric pain (e.g., in pelvic appendicitis).

Notable dullness is a characteristic sign of the presence of free fluid in the peritoneal cavity, and the sensation of a percussion wave transmitted through the fluid may be felt.

The *inspiratory sign of Murphy* can be demonstrated in acute cholecystitis. The patient is asked to take a deep breath while pressure is applied below the right costal margin. As the liver descends, the inflamed gall bladder is brought in contact with the depressed abdominal wall, and sharp pain is produced, causing immediate arrest of the inspiration.

In eliciting *Rossignol's sign*, even pressure is exerted over the descending colon, thus forcing gas around into the cecum, and pain is experienced in the right lower quadrant. This sign

is commonly present in appendicitis and indicates that inflammation of the cecum is present.

A *bluish discoloration* of the umbilicus and in the surrounding skin is occasionally found in cases of intra-abdominal hemorrhage. This is observed most frequently after rupture of an ectopic gestation and is called *Cullen's sign*.

Severe irritation of either the right or left half of the diaphragm produces pain referred to the corresponding shoulder. Examples are pain in the right shoulder with acute cholecystitis and pain in the left shoulder with ruptured spleen.

Fig. 462—The maneuver in the obturator test to stretch the obturator internus muscle.

Fig. 463—Percussion wave through free fluid in the peritoneal cavity.

LABORATORY AIDS

A complete *urinalysis* must always be carried out. Red blood cells are usually found in the urine in renal colic due to a stone and may be found in acute appendicitis. The presence of sugar in the urine is suggestive of diabetes mellitus, whereas pus cells and bacteria will lead the examiner to suspect the presence of urinary tract infection.

The *leukocyte count* is often of diagnostic importance but is occasionally unchanged in the early stages of an infective lesion, such as appendicitis or cholecystitis. Leukocytosis may be marked when an abscess or peritonitis is present. In suppurative lesions there is a relative increase in the polymorphonuclear leukocyte count. Leukopenia is characteristically found in typhoid fever and influenza.

The *hemoglobin level* should be determined in every case. It will be low after hemorrhage, provided that sufficient time has elapsed to permit hemodilution to occur. If dehydration is present, hemoconcentration is associated with elevation of the hemoglobin level and hematocrit reading.

When the presence of acute pancreatitis is suspected, an immediate *serum amylase* determination is of great value in confirming or excluding the diagnosis. It must be realized, however, that other conditions are occasionally accompanied by a significant elevation of the serum amylase level and that it may be normal or subnormal in the presence of extensive necrotizing pancreatitis.

ROENTGENOGRAPHIC EXAMINATION

Roentgenographic examination is often of great value in making or confirming the correct diagnosis of an acute abdominal condition. It is not always necessary, when the diagnosis is obvious or certain, but often provides much useful information (e.g., distention of coils of bowel and the presence of fluid levels in intestinal obstruction, separation of the gas bubble of the stomach from the diaphragm due to the presence of free blood after splenic rupture). X-ray films of the chest may reveal pulmonary disease which is not detectable by physical examination. Free gas in the perito-

neal cavity can almost always be detected by x-ray examination. When abdominal films are made, three projections should be used; i.e., in addition to a film with the patient supine, one should be made in an anteroposterior direction with the patient lying on his left side. If his condition permits, a film with the patient in an upright position should also be made. By such multiple exposures, shadows of free gas in the peritoneal cavity, gas-fluid levels in distended bowel or abscess cavity, radiopaque bodies, and soft tissue masses may be inspected and intelligently interpreted.

KNOWLEDGE OF ANATOMY AND PHYSIOLOGY

The examiner's knowledge of anatomy and physiology is often of aid in the interpretation of the physical signs and symptoms. From the anatomic point of view, the relationship of the abdominal organs to the parietal peritoneum and extraperitoneal structures should be carefully considered in every case of acute abdominal disease. Space-occupying or inflammatory lesions affect these structures and so produce symptoms and signs. Inflammation of the tissues adjacent to the psoas, quadratus lumborum, diaphragm, obturator internus, and anterior abdominal wall muscles causes irritation and reflex spasm which can be detected by examination. Examples include rigidity of the anterior abdominal muscles in acute peritonitis, a positive obturator test in pelvic appendicitis or acute salpingitis, and rigidity of the quadratus lumborum muscle in the presence of perinephric abscess. Knowledge of normal and abnormal physiology permits correct interpretation of many findings, such as the abdominal silence in paralytic ileus, the urinary frequency in pelvic peritonitis, and the pain in obstruction of a hollow viscus.

AWARENESS OF DIAGNOSTIC POSSIBILITIES

Nonsurgical abdominal diseases and extra-abdominal conditions must be excluded in the differential diagnosis of acute abdominal conditions. In order to do this the examiner must be aware of the *methods* of detecting their presence. Possession of a broad concept of the

various possibilities permits the examiner to come to a definite conclusion regarding the diagnosis, in most instances. Failure to consider possibilities is a common and serious error. Typical conditions are acute pancreatitis, acute tuberculous peritonitis, pleurisy, lead poisoning, and small bowel obstruction

The following classification of acute abdominal conditions and disorders which may simulate them is made partly on an anatomic basis. The conditions listed in italics are those for which immediate or early operative treatment is usually necessary

Acute Abdominal Conditions

- I STOMACH AND FIRST PART OF DUODENUM
 - 1 *Perforated ulcer*
 - 2 *Massive hemorrhage*
 - 3 Acute dilatation of stomach

 - 8 *Ruptured diaphragm*

Conditions Which May Simulate Acute Abdominal Conditions

- 1 Pneumonia and pleurisy
- 2 Coronary occlusion
- 3 Diabetic acidosis
- 4 Peritonitis nodosa
- 5 Tabes dorsalis
- 6 Lead poisoning
- 7 Herpes zoster
- 8 Influenza
- 9 Typhoid fever
- 10 Food poisoning and acute gastroenteritis
- 11 Blood disease (leukemia)
- 12 Tuberculous peritonitis

ACUTE ABDOMINAL CONDITIONS

STOMACH AND FIRST PART OF THE
DUODENUM

Perforated Ulcer

Perforation of a duodenal or gastric ulcer into the general peritoneal cavity is a sudden catastrophe. Delay in diagnosis and treatment may lead to the death of the patient. In some cases there is a history of symptoms of peptic ulcer or gastric carcinoma, but quite frequently there are few if any previous symptoms recalled by the patient. The signs and symptoms vary according to the period of time that has elapsed after occurrence of the perforation.

There are three generally recognized stages in a typical case. The *stage of prostration* is characterized by sudden agonizing epigastric pain which rapidly spreads over the entire abdomen, although often it is more marked on the right side. The extremities soon become cool or cold, there is marked perspiration, particularly about the face and neck, and the patient becomes livid or ashen in appearance. The expression becomes very anxious, and vomiting may occur. The vomitus contains undigested food and gastric juice, with or without blood-staining. The temperature is usually subnormal, the pulse small and thready, the respiratory movements entirely thoracic, and the blood pressure lowered. Characteristically, there is pain on the top of one (usually the right) or both shoulders. The knees are frequently drawn up in an effort to relieve the intense abdominal pain, and examination reveals extreme rigidity of the abdominal muscles and epigastric retraction. The patient lies perfectly still and avoids movement or change of position, because movement intensifies his terrible pain and may force him to cry out.

If sufficient gas has escaped into the peritoneal cavity through the perforation, there will be signs of pneumoperitoneum and consequent loss of liver dullness. The abdomen is tender throughout and often markedly so toward the right side. Examination of the rectum will reveal tenderness of the pelvic peritoneum. Peristaltic sounds diminish quite soon after the perforation occurs owing to

the inflammatory reaction which is set up by the presence of irritating gastric and duodenal contents in the peritoneal cavity.

The stage of prostration and shock passes off within a few minutes or an hour or two (depending upon the size of the perforation and the nature of the contaminating material) and merges into the so-called *stage of reaction*. The patient feels a little better, the symptoms of shock abate, and the temperature rises to normal. This is a dangerous latent period in which the unwary examiner may be lulled into a false sense of security. However, the pathologic process progresses relentlessly. During this stage the improvement is only relative

Fig 461—Area of resonance over lateral aspect of right lobe of liver as patient lies on left side, diagnostic of free gas in peritoneal cavity.

and abdominal pain continues. Examination reveals persistence of abdominal pain, rigidity, and tenderness, the respirations remain shallow and thoracic, the pelvic peritoneum becomes increasingly tender, and free gas and fluid in the peritoneal cavity may be detected. X-ray films of the abdomen will then confirm the presence of free gas, although, in approximately one fifth of the patients, free gas cannot be demonstrated. Movable dullness in the flanks may be demonstrable. An area of resonance over the lateral aspect of the right lobe of the liver, when the patient lies on his left side, is indicative of free gas over the liver. If previous peritonitis has resulted in adhesions in this region, this sign will be absent, and the presence of free gas will be revealed only by x-ray examination.

nal wall decreases, but the pelvic peritoneal tenderness persists.

There are four relatively common conditions which must be differentiated from perforated gastric or duodenal ulcer for which operative treatment is contraindicated. Biliary colic may involve severe abdominal pain and collapse but does not cause free gas in the peritoneal cavity, a tender pelvic peritoneum, or signs of severe generalized peritoneal irritation. A history of previous attacks of typical pain and jaundice is helpful. The pain of biliary colic radiates to the subscapular region. Concurrent jaundice indicates the true diagnosis.

Renal colic does not produce free gas, generalized peritoneal irritation, or tenderness

Fig. 465 —Palpation per rectum of pelvic peritoneum containing irritating fluid

The shoulder pain usually persists and, if bilateral, is suggestive of an anterior gastric perforation with irritation of both halves of the diaphragm. This pain is referred along the course of the supraclavicular nerves (C4), because sensory fibers of the phrenic nerve from the same spinal nerve roots are stimulated.

The final stage is that of *acute generalized peritonitis* characterized by distention, hic-cough, paralytic ileus, and frequent vomiting. The tenderness of the abdomen increases, the temperature may be normal, subnormal, or elevated, there may be chills, the pulse is very rapid and small, and the respirations are labored and rapid. The rigidity of the abdomi-

nal wall decreases, but the pelvic peritoneal tenderness persists. Previous episodes of hematuria or passage of a renal stone and radiation of the pain to the external genitalia are suggestive of the diagnosis. Hematuria is very significant, and radiologic visualization of the stone is diagnostic.

Acute bilateral or right-sided pleurisy may cause severe abdominal pain, but pulmonary signs will usually be detectable. Movement of the alae nasi and a rapid respiratory rate are suggestive of pulmonary disease. There will be no tenderness of the pelvic peritoneum, no free gas in the peritoneal cavity, and an x-ray film of the chest will reveal the pulmonary lesion.

In acute pancreatitis there may be agonizing abdominal pain, usually confined to the

epigastrium, with radiation to the back. Abdominal rigidity is not generalized and is rarely constant. A significantly elevated serum amylase level confirms the diagnosis. Free gas and tenderness of the pelvic peritoneum are absent, but vomiting and shock may be severe.

There are four other acute abdominal conditions which must be differentiated from perforated ulcer. Acute appendicitis with perforation can be differentiated by considering the history, the sequence of symptoms, and the local signs. The symptoms are rarely as severe as those of the initial stage of perforated ulcer but may be confused with those of the stage of reaction, especially if the perforation is small and the fluid trickles slowly down the

Fig 466—Spread of irritating fluid down right paracolic gutter from small perforation of ulcer

right paracolic gutter into the right iliac fossa and pelvis. However, in appendicitis there is no loss of liver dullness, rarely any shoulder tip pain, no persistent tenderness over the duodenum or stomach, and no detectable free gas in the peritoneal cavity.

Intestinal obstruction presents no problem of differentiation except when the patient is first seen long after the onset of symptoms. Acute strangulation of bowel may lead to free fluid in the peritoneal cavity, collapse, severe pain, and repeated vomiting. In obstruction the

vomitus becomes feculent. In the later stages both present the picture of peritonitis, but free gas in the abdomen will not be found in obstruction unless gangrenous bowel has ruptured.

Peritonitis due to other causes is differentiated by the history and the absence of free gas in the abdomen. It may be impossible to differentiate peritonitis due to perforation of other parts of the intestine.

In females ruptured ectopic gestation with massive hemorrhage into the abdominal cavity frequently leads to severe abdominal pain, vomiting, and collapse. A history of amenorrhea may be helpful but not diagnostic. Signs of massive hemorrhage with blanching of nails, lips, and mucous membranes are important findings. The pelvic peritoneum will be tender and free fluid demonstrable in the abdomen, but true loss of liver dullness does not occur, although shoulder tip pain from irritation of the diaphragm by blood may be a complaint.

It must be realized that *localized peritonitis or subphrenic abscess*, alone, may follow perforation of an ulcer. This may occur if the leak is very slow or is into the lesser peritoneal sac, permitting time for sealing-off from the general peritoneal cavity by fibrin deposits. In such an instance the signs and symptoms may be limited and less severe, being restricted to the upper portion of the abdomen, and the clinical picture will be that of subphrenic abscess (see Chapter 23, Peritoneum, Omenta, and Mesenteries). Very infrequently a small perforation will be sealed by deposition of fibrin and resolve after temporary signs and symptoms of upper abdominal irritation resembling those of acute cholecystitis or mild acute pancreatitis have disappeared.

Massive Hemorrhage

Massive hemorrhage from the stomach or first part of the duodenum is an acute abdominal condition easily diagnosed in most instances. The combination of hematemesis, hyperperistalsis, gross melena, and symptoms and signs of hemorrhagic shock is unmistakable. The history often provides evidence of previous hemorrhage, the peptic ulcer syndrome, or deterioration suggestive of a gastric

esophasm. It must be differentiated from hemorrhage from esophageal varices which is a complication of portal hypertension. In the latter condition, symptoms and signs of portal hypertension, hepatic cirrhosis, or splenomegaly may be present. It is absolutely essential to determine the presence or absence of esophageal varices as early as possible by means of x-ray examination of the esophagus or, if need be, by esophagoscopy examination in the operating room after preparations for parotomies have been made and anesthesia induced.

Acute Dilatation of the Stomach

This is a condition in which there is sudden enormous distention of the stomach due to accumulation of fluid and gas. It is characterized by effortless regurgitant vomiting, absence of peristaltic sounds, rapid dehydration, hypochloremic alkalosis with or without tetany, and severe collapse owing to oligemic shock. Epigastric pain may be present or absent. This condition is rapidly fatal if not relieved. The diagnosis is obvious when it occurs during an abdominal operation, owing to the swallowing of air or forcing of gas into the stomach under pressure. It usually follows abdominal operations and may be looked upon as a special variety of paralytic ileus, but it may occur in other illnesses (e.g., after trauma, during an acute febrile illness). The epigastric and lower left chest are resonant, and the heart is displaced upward and to the left. Succussion splash may be demonstrated, and there is no abdominal rigidity. The vomitus consists of decomposing gastric, duodenal, and biliary secretions which gradually become rankish. Aspiration of gastric contents is the therapeutic and diagnostic test. The aforementioned characteristics of acute gastric dilatation differentiate it from high small bowel obstruction, peritonitis, uremia, drug poisoning, and intra-abdominal hemorrhage.

Volvulus of the Stomach

Volvulus of the stomach is an abnormal anterior or posterior rotation of a portion or the whole of the stomach about either the transverse or sagittal axis of its body (Maignot). It is extremely rare and cannot occur unless

the ligamentary supports of the stomach are abnormally long. The clinical features of acute volvulus are characteristic. Early vomiting is followed by intractable retching and inability to vomit. There is rapidly increasing distention limited to the epigastrium with simultaneous retraction of the lower abdominal wall. It is impossible to pass a tube into the stomach. These findings are due to initial pyloric obstruction followed by obstruction of the cardia and distention of the stomach by gas and fluids (closed-loop obstruction). The patient suddenly experiences agonizing epigastric pain radiating through to the back. If it is not relieved, signs of hypotensive shock soon appear. The only other condition requiring differentiation is *acute gastric dilatation*, which can be relieved by the passage of a gastric tube and aspiration of gastric contents. X-ray examination of the abdomen will reveal gastric distention with a gas-fluid level.

Acute Phlegmonous Gastritis

This extremely rare condition is a severe diffuse or localized inflammatory process involving the gastric submucosa which progresses to pus formation and perhaps necrosis of the gastric wall. It is difficult to diagnose. In the fulminating type of case the symptoms are those of acute toxemia, whereas the signs are those of peritonitis. Vomiting is intractable and the vomitus is blood-stained purulent material. There are hyperpyrexia, rapid pulse, marked leukocytosis, dry coated tongue, and epigastric rigidity and tenderness. Deterioration is rapid, and death ensues within a few days unless prompt treatment is given.

This condition must be differentiated from perforated peptic ulcer, acute pancreatitis, acute cholecystitis, pyogenic liver abscess, and hematogenous streptococcal or pneumococcal peritonitis. In phlegmonous gastritis a barium meal x-ray examination reveals an intact mucosa but a greatly thickened gastric wall. Perforated ulcer is differentiated by the presence of free gas in the peritoneal cavity and pancreatitis by the local signs and elevated serum amylase. Acute cholecystitis and liver abscess are differentiated by the local signs, history, and character of the vomitus. Primary peritonitis is differentiated by the history, local signs, and pure

culture of the causative organism from the peritoneal exudate aspirated by means of a needle.

SMALL INTESTINE

Acute Obstruction

Once complete obstruction of the intestine develops, death will inevitably result unless there is spontaneous correction of the condition, formation of an external fistula, or operative relief. Early diagnosis and treatment are essential because the mortality rate rises with each hour of delay. The symptoms vary in severity with the level at which the intestine is obstructed and are generally considered in relation to *high* or *low* small bowel obstruction. The onset of symptoms is slower the lower the level of obstruction. The obstruction tetrad of *crampy pain*, *vomiting*, *gradually increasing distention* and *obstipation* is usually present, although only one or two components may be apparent in the early stages. When there is strangulation of a segment of gut, the onset is very acute with severe symptoms: pain, shock, early vomiting, abdominal tenderness, and visible peristalsis. *Teculent vomitus*, in the absence of advanced peritonitis, is characteristic of obstruction. Abdominal distention is not a prominent feature in early cases, especially if the point of obstruction is high, but always appears later. The outline of distended loops of small bowel may be visible or palpable, particularly in *volvulus* about an adhesive band. X-ray films of the abdomen are invaluable in revealing the extent of distention, the approximate site of obstruction, and the presence of fluid levels. Sigmoidoscopy and a barium enema x-ray examination will exclude obstruction of the large bowel. In advanced stages of small bowel obstruction there is evidence of rapidly increasing dehydration and toxemia, which progress to collapse, coma, and death if not relieved (see Chapter 24, Intestinal Obstruction). When there is strangulation of gut (*hernia*, *volvulus*), the abdominal tenderness is marked, peristalsis is inhibited or absent (*paralytic ileus*), vomiting is very severe, a tender mass may be palpable, and early fever and leukocytosis develop.

It may be impossible to differentiate the various forms of small bowel obstruction be-

fore exploratory laparotomy is performed. However, an incarcerated or strangulated external hernia can be diagnosed immediately by physical examination, and x-ray films may reveal a radiopaque foreign body such as a calcified gallstone in the small bowel (most frequently arrested in the ileum). *Intussusception* is usually found in the distal ileum and most commonly occurs in children under 2 years of age. The findings of a sausage-shaped mass in the abdomen, together with the passage of bloody stool in the presence of low small bowel obstruction, are diagnostic and a tender pelvic mass may be palpable on rectal examination. A barium enema x-ray examination will demonstrate the intussusception if it is of the ileocolic variety.

The differentiation of small bowel obstruction from *acute inflammatory abdominal conditions* may be difficult or impossible and they often coexist. Inflammatory conditions often cause secondary paralytic ileus even though the lumen of the gut is not obstructed (e.g., acute appendicitis, acute salpingitis).

Simple *constipation* can usually be diagnosed by the presence of impacted feces in the rectum. *Renal colic* and *biliary colic* are differentiated by the type of pain and local findings. *Acute pancreatitis* can be diagnosed by the history, local findings, and an elevated serum amylase level. *Acute coronary occlusion* is differentiated by the history, physical signs, and electrocardiographic changes, although it may be accompanied by a degree of paralytic ileus. *Acute pulmonary conditions* may cause unilateral upper abdominal pain but not the other signs of intestinal obstruction. *Enterocolitis* and *food poisoning* usually produce characteristic symptoms and signs, and the history combined with copious, often persistent, diarrhea differentiate them from bowel obstruction.

Regional Enteritis

An acute attack of this condition frequently produces right lower quadrant abdominal pain, fever, and leukocytosis. The pain is often *crampy* and may be associated with diarrhea, nutritional disturbances, and partial or complete intestinal obstruction. A tender mass may sometimes be palpated in the right lower quadrant. If perforation of the ileum occurs

there will be signs of acute localized peritonitis, since the process is usually limited by inflammatory adhesions

It may be impossible to differentiate regional enteritis from *appendicitis* or active *ulcerative colitis*. If confused with the former it will be diagnosed at operation, and if confused with the latter it may be recognized by barium x-ray studies of the intestines

Careful consideration of the history, the appearance of a complicating fistula, together with a high index of suspicion, will often lead to the correct diagnosis. Acute regional enteritis must also be distinguished from *tuberculous enteritis*, *actinomycosis* of the ileocecal region, *diverticulitis* of the ascending colon or cecum, and *ulcerated neoplasms* of the small intestine and cecum

Meckelian Diverticulitis

Acute inflammation, with or without perforation, of a Meckel's diverticulum can seldom be differentiated from *acute appendicitis*, and the differential diagnosis will be dealt with under that heading

Perforation of Small Intestine

This acute abdominal condition may be caused by a variety of disease processes and by trauma. The characteristic history of the causative lesion, together with signs and symptoms of acute peritonitis from rupture of a hollow viscus and the presence of pneumoperitoneum, lead to the correct diagnosis. However, evidence of a perforated viscus is an absolute indication for early laparotomy by means of which the diagnosis can be confirmed and the lesion identified

LARGE INTESTINE

Acute Obstruction

Acute obstruction of the large bowel may be caused by a variety of lesions. The commonest cause is *sarcinoma*, which may produce sudden complete obstruction to the passage of both stool and gas, although there are usually symptoms of previous partial obstruction. In general, large bowel obstruction requires a longer time to produce serious signs and symptoms than does small bowel ob-

struction, although the clinical picture is quite similar in the later stages. It is characterized by enormous abdominal distention, particularly if the lesion is situated in a distal segment, owing to the distensibility of the voluminous cecum and colon and to distention of the small gut when the ileocecal valve is incompetent. Gas- and fluid-filled colon may be outlined by palpation and percussion in many instances. *Closed-loop obstruction* is a special type in which the ileocecal valve remains competent and the distention is limited to the cecum and colon proximal to the lesion. In this type, early recognition and treatment are necessary to avoid the complication of extreme cecal distention resulting in ischemic necrosis of its wall and perforation. In such a case there may be few physical or roentgenographic signs of small bowel distention. Vomiting of a reflex nature may occur early, but true obstructive vomiting appears late and may be minimal or even absent despite great abdominal distention and circulatory collapse owing to the pooling of fluid and electrolytes in the distended intestine. Visible peristalsis, loud booming peristaltic sounds, and a succussion splash on shaking the patient are often found.

Volvulus of the cecum or pelvic colon produces acute, severe symptoms and signs, and surgical treatment is urgently required. In the former, there is closed-loop obstruction of the cecum and part of the ascending colon with simple obstruction of the ileum. The large tympanic mass of dilated cecum may be outlined visually by palpation and by percussion as it extends upward toward the left upper quadrant of the abdomen. Reflex vomiting may be frequent and copious from the outset, followed later by the vomiting of feculent material due to ileal obstruction. Change of position may increase the pain, owing to stretching of the twisted mesentery, and it may radiate to the back

In *volvulus* of the pelvic colon the distended, closed loop of colon rises out of the left side of the pelvis and projects toward the right upper quadrant. Here, too, the closed loop obstruction is associated with simple obstruction of the proximal colon

In *volvulus* of the cecum or pelvic colon early strangulation leading to gangrene and

perforation may occur. As strangulation develops, signs of an acute intraperitoneal inflammatory process appear, including those of paralytic ileus, peritonitis, leukocytosis, and rising pulse rate and temperature. In all cases of large bowel obstruction x-ray examination is diagnostic, particularly when a barium enema is introduced. The diagnosis of an obstructive lesion may be made by sigmoidoscopic examination when it is within reach of the instrument. Occasionally a rectal tube can be carefully inserted through a sigmoidoscope in volvulus of the pelvic colon, releasing the confined gas and fluid, leading to nonoperative reduction of the torsion.

Obstruction due to adhesions usually follows previous abdominal surgery or peritonitis, and its exact nature is determined at laparotomy.

Inflammatory stenosis of the large bowel may be caused by a variety of lesions, prominent among which is acute diverticulitis of the pelvic colon. Another example is postirradiation stenosis of the pelvic colon or rectum following treatment of carcinoma of the uterine cervix.

Paralytic ileus causing obstruction of the colon is just part of the condition involving both large and small intestine when peritonitis is present (see Chapter 24, Intestinal Obstruction).

Fecal impaction is an unusual cause of acute large bowel obstruction but can be diagnosed by the history and rectal examination.

The large bowel (principally the cecum and pelvic colon) may become obstructed when a segment is caught in an internal or external hernia (incarcerated hernia).

Intussusception of the colon can be diagnosed by symptoms and signs of large bowel obstruction, palpation of an elongated mass in the course of the colon, the passage of bloody material per rectum, and barium enema x-ray examination.

Foreign bodies occasionally cause obstruction if they become impacted in a stenotic segment of colon, at the normally narrow pelvicrectal junction, or at the upper end of the anal canal. The diagnosis of the latter is confirmed by rectal examination and of the former by roentgenographic examination.

Perforation of Large Intestine

Perforation may be traumatic, inflammatory, or neoplastic. *Traumatic perforation* is caused by perforating or penetrating wounds, foreign bodies introduced per rectum, or blunt trauma. *Inflammatory perforation* may result from diverticulitis, obstruction with gangrene, or ulcerative colitis. *Neoplastic perforation* of the colon occasionally occurs. The history and physical signs of a perforated hollow viscus with rapidly developing, severe septic peritonitis and pneumoperitoneum are characteristic. Determination of the site of perforation may be made from the early signs, but, later, generalized peritonitis may make this impossible before abdominal exploration is performed. It must be differentiated from perforated peptic ulcer and perforated appendicitis.

Diverticulitis of the Colon

Diverticulitis may produce either obstructive or inflammatory symptoms. When obstruction is present, the clinical picture resembles that of obstructive carcinoma. When local inflammation or abscess develops, the symptoms resemble those of pelvic appendicitis, and certain diagnosis before operation may not be possible because a barium enema in these circumstances is inadvisable. A history of previous bowel symptoms, with attacks of diarrhea or constipation or blood and mucus in the stool, may be suggestive. The pain of *appendicitis* usually begins in the epigastrium, that of pelvic diverticulitis in the hypogastrium.

APPENDIX

Acute Appendicitis

It is generally recognized that every patient with acute appendicitis should be operated upon at the earliest possible moment, in order to reduce the mortality and morbidity of this progressive disease. The commonest reasons for delay are procrastination on the part of the patient or his medical adviser. Experience has shown that it is impossible to predict the severity of an attack at its onset. The pathologic changes present depend upon so many different local circumstances that there may be little correlation between them and the signs and symptoms produced.

The position of the appendix varies greatly from case to case, both in the direction it extends from its cecal attachment and in the position of the cecum itself (see Chapter 25, Appendix). Before considering the diagnosis of appendicitis in a patient with an abdominal scar, it is well to make certain that the organ is present. Conversely, a patient may mistakenly believe that the appendix has been removed during a previous operation (e.g., cholecystectomy). If the diagnosis seems clear it is better to operate than to depend on the patient's declaration that the organ has been removed.

The history of the onset of symptoms should be carefully considered as well as the remote history (frequently there have been previous attacks of pain in the appendiceal region). Preceding subacute attacks have often been looked upon by the patient as due to acute indigestion.

Common symptoms and signs include pain, vomiting, low-grade fever, local abdominal tenderness, and preceding constipation. Inconstant findings are rigidity of muscles, hyperesthesia, slight distention, and testicular symptoms in the male.

Early pain is usually experienced in the epigastrium or generally in the mid-abdomen, and only later does it become localized over the appendiceal area, which is usually in the right lower quadrant. This location sequence may vary considerably. The local pain may be due to appendiceal colic or to distention of the appendix by products of inflammation. The pain may be steady or there may be crampy exacerbations. Vomiting, as a rule, occurs early in this condition but may never occur, and in the latter case nausea or anorexia is just as significant. Local abdominal tenderness over the appendix is found early in the attack and is elicited best by deep palpation. This is found, classically, at McBurney's point which is situated at the junction of the lateral and middle thirds of a line joining the umbilicus and the right anterior superior iliac spine, and corresponding closely to the actual site of the appendix. It arises either from the appendix itself or from adjacent irritated peritoneum. In a child, or in an adult with the appendix in the pelvis, rectal palpation will produce pain in the region of the inflamed appendix.

The *shake test* is frequently positive, eliciting pain over the inflamed appendix. Hypertesthesia of the skin of the abdominal wall on the right side can often be found in the distribution of the cutaneous branches of the 10th and 11th thoracic nerves. It is most commonly found just to the right of and below the umbilicus (T10).

In acute appendicitis there is almost always local muscular rigidity, which varies greatly in intensity, although this sign may not be present early in the disease. If very severe, it is suggestive of early local peritonitis. Muscular

Fig. 467.—Rovsing's sign. Compression of the descending colon forces gas into inflamed cecum, causing right lower quadrant pain.

rigidity may be absent, particularly if the appendix is pelvic or retrocecal in position. Psoas spasm is frequently found. In pelvic appendicitis the *obturator test* may be positive, and in high positions of the inflamed appendix, rigidity of the quadratus lumborum is common. *Rovsing's sign*, when present, is very suggestive.

Fever usually appears before the first day has passed and is low-grade. Occasionally fever may not appear, or it may be very high, particularly in young children. Chills are infrequent but may occur early in the disease. Pre-

APPENDIX

ceding constipation is the rule, but the bowel movements may have been regular or diarrhea may have occurred. The pulse rate is normal initially but accelerates with the development of peritoneal irritation or frank peritonitis. Cecal gurgling on palpation indicates a form of distention owing to atony, possibly a local localized paralytic ileus. Males occasionally have testicular pain accompanied by retraction of the right testicle, probably because both the testicle and the appendix are supplied by the 10th thoracic spinal segment.

The time sequence of symptoms and signs is of considerable importance in diagnosis. The usual sequence is as follows: pain, nausea or vomiting, local tenderness, fever, and leukocytosis. Leukocytosis is usually present but may be minimal or absent, particularly in elderly patients. It is frequently of great value to determine the position of the cecal gas shadow by means of x-ray films of the abdomen.

The preceding description applies to acute appendicitis, before perforation has occurred, but after perforation the picture is greatly altered. Since this is an advanced stage of the disease, the signs and symptoms are those described above plus those of either local or diffuse peritonitis. After perforation the pain increases and may spread widely throughout the abdomen, accompanied by increased, or the abdomen, accompanied by increased, or the recurrence of, vomiting. The signs of paralytic ileus soon appear if diffuse peritonitis ensues. When the peritonitis is localized, limited by omentum or bowel, a mass develops and is referred to as an *appendiceal abscess*. Such localized peritonitis varies in site according to the position of the cecum and appendix and may be *sitac*, retrocecal, paracecal, medial to the cecum, behind the terminal ileum, pelvic, or elsewhere in the abdomen. The physical findings will vary with its position and the contiguous structures irritated (e.g., retrocecal appendix causing psoas rigidity, medially situated appendix causing ureteral irritation and ated appendix causing ureteral irritation and dysuria, paracecal appendix causing loin tenderness and quadratus lumborum rigidity). Characteristically, when there is a pelvic appendiceal abscess there are bladder and rectal irritations, and the tender bulging mass is palpable per rectum. Later on, in the presence of an appendiceal abscess, especially if it is lo-

cated in the pelvis, the small or large intestine may become secondarily obstructed.

Acute appendicitis is so very common that familiarity breeds contempt and the diagnosis is often made after a very perfunctory examination. This is bound to lead to errors in diagnosis and is, therefore, inexcusable.

Appendicitis must be distinguished from several other conditions. Extra-abdominal conditions include diaphragmatic pleurisy, spinal disease, and influenza. Early *basal pneumonia* with pleurisy may produce pain, tenderness, and rigidity in the right lower quadrant. The Rovsing's sign is never present. Elevation of the respiratory rate and pulse rate may be marked. Careful chest examination will make the diagnosis clear, and x-ray examination may confirm it. Abdominal pain may be prominent in influenza, but there will be signs of an upper respiratory infection and generalized muscular aches and pains. Vomiting, if it occurs, often precedes the abdominal pain. *Spinal disease*, in the form of acute osteomyelitis, may simulate appendicitis but is recognized by careful examination of the spinal column and the absence of deep abdominal tenderness.

Typhoid fever, although uncommon nowadays, may produce symptoms similar to those of appendicitis. The general malaise, splenomegaly, roseola, leukopenia, bradycardia, and history of onset serve to differentiate the two conditions.

Early appendicitis may be mistaken for *indigestion*, *intestinal colic*, or *acute gastritis*, but careful consideration of the history of onset and findings will permit differentiation.

Acute appendicitis, because its signs and symptoms are variable, may be simulated by almost any acute abdominal condition, but those that enter into the differential diagnosis vary with the position of the appendix and with the presence or absence of appendiceal perforation.

Since the duodenum, right kidney, gall bladder, and liver are near an inflamed high-lying appendix, acute conditions involving these organs must be distinguished from it. Inflammation about a *penetrating duodenal ulcer* is differentiated by the characteristic preceding history of pain, coming on 2-3 hours

after a meal, which is promptly relieved by ingestion of food or alkali.

Right-sided renal or ureteral colic, due to stone, may resemble acute appendicitis. The history and nature of the symptoms, severe colic with intervening remissions, radiation of pain into the external genitalia, hematuria, and x-ray evidence of a stone serve to identify this condition. If doubt remains, cystoscopy with retrograde pyelography will be diagnostic. *Acute right-sided hydronephrosis* produces a swelling, palpable in the side of the abdomen and loin, which is tense, tender, and rounded and may be mistaken for an appendiceal abscess. However, such a mass is movable and will be associated with urinary symptoms. Abdominal rigidity will not be persistent. *Acute pyelitis* on the right side is frequently confused with appendicitis but can be identified by frequent rigors early in the disease, high fluctuating fever, dysuria, urinary frequency, pyuria, and bacilluria. The abdominal muscles are not rigid.

Acute cholecystitis may be indistinguishable from appendicitis, especially when the elongated and inflamed gall bladder descends into the right iliac fossa. If muscular rigidity is not too great and the abdominal wall thin, the diagnosis may be confirmed by palpation of the tender gall bladder which moves with the liver during respiration. Pain may be referred to the right subscapular region (and shoulder), and there is never resonance over an enlarged gall bladder because it lies anterior to the colon. If gall bladder colic is experienced simultaneously and a past history of gall bladder symptoms is obtained, cholecystitis may be identified with certainty. Noticeable jaundice and bile in the urine are additional diagnostic features.

Strangulation of the omentum or of an *epiploic* appendix by acute torsion may simulate appendicitis by the production of pain and tenderness to the right of the umbilicus and differential diagnosis may not be possible.

Perinephric abscess of metastatic origin may resemble an abscess due to appendiceal perforation. The history of onset without the typical features of the development of appendicitis serves to differentiate it.

When the appendix is in its common iliac position, several other conditions must be seriously considered in the differential diagnosis.

Carcinoma of the cecum or of the right half of the colon, which has become ulcerated and has perforated the wall, producing an abscess, may simulate appendiceal abscess. The differentiation may be impossible but the history may suggest the true diagnosis. *Ileocecal tuberculosis* and *acute regional ileitis* may also be indistinguishable prior to operation. Another condition which causes similar symptoms is *acute mesenteric lymphadenitis*, but in this case differentiation is only academic, as appendectomy is the treatment of choice for both conditions.

Perforated duodenal ulcer with slow leak of bowel contents down along the ascending colon into the iliac fossa and pelvis may resemble appendicitis. However, the onset is sudden, the initial shock often severe, and pneumoperitoneum definitely distinguishes it.

Rupture of the right rectus muscle or development of an *abdominal wall abscess* can be differentiated by the history and local findings.

When the appendix is situated in the *pelvis*, the differential diagnosis of appendicitis in the female differs from that in the male. In both sexes *diverticulitis* of the colon, *bowel obstruction*, and *ureteral stone* often present problems of differential diagnosis. In *obstruction of the small bowel* characteristic distention and peristaltic sounds are present, as well as the other findings, so that it may be clearly differentiated from appendicitis. *Large bowel obstruction* in the pelvis may be confused with pelvic appendicitis but can be differentiated by the history, findings, and the presence of early distention which is uncommon in appendicitis. *Diverticulitis of the pelvic colon* may cause obstructive or inflammatory symptoms. When an abscess develops, the findings closely resemble those of pelvic appendicitis, but the signs and symptoms are predominantly left-sided. Differentiation may be impossible prior to operation unless there have been proved previous attacks of diverticulitis.

In the female, acute conditions involving the pelvic generative organs must be differentiated from acute pelvic appendicitis (see Chapter 28, Female Genital Tract). *Threatened abortion* can be identified by the history of amenorrhea, uterine bleeding, nature of the pain, and absence of local signs of appendicitis. In *ectopic gestation* (with hemorrhage) anemia, a

displaced uterus and the absence of the symp-

it The former rarely causes epigastric or generalized abdominal pain but usually causes bilateral hypogastric pain from the beginning. The presence of vaginal discharge is helpful, as is the pelvic examination. The true diagnosis may not be reached prior to operation, but laparotomy is less dangerous than delay in treatment of acute appendicitis.

Other gynecologic conditions easily confused with appendicitis are *ovarian cyst*, *hydrosalpinx*, and *leiomyoma with a twisted pedicle*. In such an instance pain and vomiting occur almost simultaneously, and nausea is very severe and persistent. A movable rounded pelvic mass may be demonstrable by vaginoabdominal palpation.

Once diffuse or general peritonitis, caused by appendicitis with perforation, has become established, specific diagnosis may be impossible. The diagnosis of peritonitis will be relatively simple, but the possible causes will include *primary peritonitis* (pneumococcal, streptococcal), *secondary peritonitis* of other origin, *mesenteric vascular occlusion*, *advanced acute intestinal obstruction*, *severe pylephlebitis*, and *acute pancreatitis*. Primary peritonitis can be identified by pure culture of the offending organism from the intraperitoneal fluid and pancreatitis by the elevation of the serum amylase. Identification of other causes may be possible on the basis of the history of the illness.

GALL BLADDER

Acute Cholecystitis

This is an acute inflammation of the gall bladder which may occur in the presence or absence of gallstones. It varies greatly in intensity from mild to very severe with gangrene of the wall. The chief symptoms are *pain*, *vomiting*, and *fever*. The *pain* varies considerably, especially when a stone causes simultaneous gall bladder colic. It is aching in nature and accompanied by a sensation of swelling in the right subcostal region. When there is associated pericholecystitis, the pain may be diffuse in the right upper quadrant and referred to the subscapular region or to the

right shoulder. When the liver or gall bladder is greatly enlarged, the pain may extend into the right lower quadrant. *Vomiting* is variable, but in the presence of gallstones and peritonitis, nausea and vomiting may occur repeatedly. Characteristically, the *fever* is not high, rarely exceeding 103° F., but it may be irregular with accompanying chills. The *pulse* rate is often normal in cholecystitis, but an increase indicates absorption of toxic materials from the biliary tract or advancing peritonitis. *Tenderness* over the site of the gall bladder is always present, and the organ can be felt if it is enlarged and if muscular rigidity is not pronounced. An inflammatory mass occasionally develops through involvement of contiguous organs. Pericholecystitis, or localized peritonitis, produces muscular rigidity over the inflamed area. *Constipation* is frequently present, probably because of the inflammation affecting adjacent coils of bowel. *Jaundice* may accompany the attack and is caused by a gallstone in the common bile duct or by inflammatory compression of the common hepatic or bile duct producing obstruction.

Acute cholecystitis must be distinguished from *appendicitis*, *penetrating duodenal ulcer*, *biliary colic*, *pleurisy*, *pancreatitis*, and *hepatitis*. The differentiation from *appendicitis* has been discussed in the preceding section.

A *penetrating duodenal ulcer* with localized peritonitis may produce physical signs similar to those of cholecystitis, but a past history of pain coming on 2-3 hours after a meal, relieved by ingestion of food or alkali, will make the diagnosis clear. Other helpful evidence includes the occurrence of *melenas*, symptoms suggestive of pyloric spasm, and heartburn. An immediate barium meal may demonstrate the presence of the ulcer.

Biliary colic may be distinguished from cholecystitis by its acute onset and severe colicky pain. There is no abdominal wall rigidity and the patient frequently rolls about the bed in agony, whereas he tends to lie still to avoid increasing the pain of cholecystitis. The temperature is normal or subnormal, and collapse may be severe. Administration of atropine often relieves the pain promptly.

Diaphragmatic pleurisy accompanying pneumonia or pulmonary infarction produces high fever and severe chills. The abdominal tender-

ness, if present, is superficial and signs of infiltration of the base of the lung may be found. Expectoration of sputum or hemoptysis will also be suggestive of such a condition.

Acute pancreatitis may resemble cholecystitis closely or coincide with it. However, the pain of pancreatitis is in the epigastrium or to the left of the midline and usually penetrates to the back. Tenderness is found in the epigastrium and left hypochondrium and paralytic ileus frequently develops early in the disease. Collapse is often profound. The serum amylase will be significantly elevated.

Acute hepatitis is characterized by tenderness over the entire liver, including its lateral aspect. Jaundice may be evident and the urine may contain bile. The liver is often moderately enlarged and the gall bladder not palpable. Prodromal symptoms of anorexia, nausea, and vomiting for several days are typical.

Biliary Colic

This has been discussed in the differential diagnosis of acute cholecystitis. It is easily differentiated from *right renal colic* by the history and local findings, by jaundice if it is present and by examination of the urine and x-ray films.

PANCREAS

Acute Pancreatitis

This was formerly regarded as being relatively rare but it has been recognized more frequently in recent years. It is an acute abdominal condition which is often misdiagnosed because the possibility is not considered. It is particularly important to diagnose acute pancreatitis accurately since experience has shown that conservative treatment alone is indicated and operative measures should be restricted to the treatment of certain complications, such as an abscess. Acute pancreatitis is uncommon before the age of 40, and the victim is frequently obese. It often begins after the ingestion of a heavy meal, and it may or may not be associated with gall bladder disease.

The symptoms of pancreatitis vary widely in severity and variety. Pain is a constant symptom and the onset is usually very sudden. At times it is severe enough to cause collapse and

syncope. The pain is agonizing, often causing the patient to cry out. It is situated primarily in the epigastrium but may reach one or both loins. It usually radiates to the back and subscapular area on the left side. Sometimes there is pain in the left side of neck or left shoulder, referred from the irritated diaphragm. The initial intensity gradually diminishes, but the pain may be felt over the entire abdomen. Signs and symptoms of *hypotensive shock* appear unless the attack is mild. Nausea and vomiting are often constant and persistent features. The vomiting does not become feculent unless paralytic ileus supervenes. Dehydration is early and severe. *Epigastric tenderness* is almost always present and often severe, but the pelvic peritoneum is not tender. *Epigastric rigidity* is usually present, but the abdominal wall may be relaxed. The edematous pancreas is rarely palpable. In about one half of the cases *slight jaundice* is present, due to obstruction of the bile duct by the edematous pancreas or a gallstone. There may be *bluish discoloration* in the flanks and umbilical region, owing to extravasated blood and pancreatic enzymes, constituting a grave prognostic sign which occurs late in the acute hemorrhagic form. *Glycosuria* and *hyperglycemia* may be present because of interference with function of the islets of Langerhans. The serum amylase level is markedly raised and may remain elevated for a few days or fall sharply after 24-48 hours to a subnormal level. The serum lipase is usually elevated early in the disease also and remains so for several days in most instances. Depression of the serum calcium level, owing to a major degree of pancreatic destruction and fat necrosis, indicates a serious prognosis. *Leukocytosis* is usually moderate (15,000-20,000/c mm). X-ray examination of the abdomen frequently shows isolated, distended loops of small bowel (sentinel loop) containing fluid levels in the upper midzone of the abdomen. Widespread paralytic ileus often develops later.

Acute pancreatitis must be differentiated from cholecystitis, perforated ulcer, intestinal obstruction, appendicitis, mesenteric vascular occlusion, acute gastritis, and coronary occlusion. The details of the differentiation are described elsewhere in this chapter. A careful consideration of the history and findings, sup-

ported by a significantly elevated serum amylase, makes the diagnosis of acute pancreatitis certain.

LIVER

Liver Abscess

Acute liver abscess may be *amebic* or *pyogenic*. *Acute amebic abscess* is a pyrexial illness with enlargement and tenderness of the liver, and there is a history of dysentery and amebae in the stools in approximately one half of the cases. The manifestations include intermittent fever, night sweats, weakness, loss of weight, nausea, anorexia, malaise, and vomiting. Chills and mild jaundice may occur. There are right upper quadrant pain and tenderness, and limited chest movements on the right side. Pain is often referred to the right shoulder, scapular region, and iliac fossa. Local edema of the thoracic and abdominal walls is occasionally apparent. Pain is caused by sudden movements so that the patient holds the right arm close to his side. There may be congestion of the lower part of the right lung, and the right side of the diaphragm may be immobile. There is leukocytosis of moderate degree but no alteration of the differential count. X-ray films may show a soft tissue shadow of the abscess and a raised, fixed hemidiaphragm. Examination of the stool often reveals evidence of amebiasis. The diagnosis is confirmed in the operating room when pus is aspirated from the abscess. The symptoms and signs of *pyogenic abscess* are similar to those of amebic abscess, but exploratory aspiration should not be attempted because of the danger of disseminating infection in the pleural or peritoneal cavity. If a liver abscess ruptures into the peritoneal cavity acute generalized peritonitis results.

Liver abscess must be differentiated from *subphrenic abscess*, *cholecystitis*, and *perinephric abscess*. *Right perinephric* and *subphrenic abscess* may originate from a perforated retrocecal appendix or may be of metastatic origin. There is pain on pressure forward in the costovertebral angle. There are general symptoms of an acute suppurative process, but the liver will not be tender anteriorly, nor will there be nausea and vomiting.

The history of appendicitis or the presence of a focus of suppuration elsewhere may be helpful in making the diagnosis.

Rupture of the Liver

This serious condition will usually be suspected on consideration of the history of the injury. Examination may reveal abrasions or bruising over the right side of the abdomen or thorax. There are tenderness and rigidity of the overlying abdominal muscles and signs of shock due to hemorrhage. If internal hemorrhage is massive, the patient will be pale, and movable dullness will be found in the flanks. Early recognition and prompt treatment constitute the only hope of saving the life of the patient.

Rupture of the liver may be associated with damage to other viscera, so that differential diagnosis is of no importance once it is decided that serious visceral damage has been sustained and immediate laparotomy is necessary.

Acute Hepatitis

This may produce symptoms and signs of an acute abdominal condition, especially in young individuals. It is characterized by *tenderness* over the whole liver, including its lateral aspect. There is usually a history of *anorexia*, with or without nausea and vomiting, over a period of days before acute symptoms develop. The *temperature* may be normal or slightly elevated, and leukocytosis is *moderate*. Often there is no abdominal wall rigidity, but there may be muscle guarding on palpation over the tender, enlarged liver. Often there is *jaundice* and *bile in the urine*. Acute hepatitis must be distinguished from *cholecystitis*, which does not produce tenderness over the whole liver.

SPLEEN

Rupture of the Spleen

Spontaneous rupture of a diseased spleen occasionally occurs, but usually there is a history of trauma. The injury may have been *minor*, or there may have been a serious injury sustained in the region of the left upper abdomen or chest. The symptoms are those of rapid and profound collapse due to internal hemorrhage. If treatment is not immediately

available death will ensue; in fact death from hemorrhage may occur within a few minutes, before anything can be done. The chief diagnostic features are *local pain* in the left upper quadrant, *free blood in the abdomen* (pain, ileus, distention, rigidity, movable dullness) and *hemorrhagic shock*. Other characteristic signs are *left shoulder pain*, *tenderness in the left flank*, *muscular guarding* in the left flank, a *mass* in the splenic region, *low-grade fever*, *pallor*, and *slight jaundice*. The pain is continuous. If hemorrhage is massive, movable dullness may confirm the diagnosis. Other viscera may be seriously damaged by an injury causing splenic rupture. The differential diagnosis of rupture of the spleen is of little importance. If it is suspected, immediate laparotomy is urgently indicated.

Splenic Infarct

Embolism of the splenic artery or one of its branches produces a splenic infarct. This usually occurs in an enlarged abnormal spleen. It causes sudden severe pain in the splenic region and sudden increase in the size of the spleen. A friction rub may be heard over the spleen, owing to the formation of an inflammatory exudate on its serosal surface. Evidence of embolism elsewhere and of auricular fibrillation is helpful in the diagnosis. It can be differentiated from splenic rupture by noting the absence of a history of trauma and hemorrhagic shock. *Delayed splenic rupture* (intra-splenic hematoma) may be difficult to differentiate if a source of emboli cannot be found.

PERITONEUM

Acute Peritonitis

Acute peritonitis is a very common accompaniment of many acute abdominal conditions. Streptococcal and pneumococcal peritonitis are hematogenous and are designated *primary peritonitis*. Bacteria may reach the peritoneal cavity by rupture of a viscus, by passing through the wall of a diseased viscus, or through a penetrating abdominal wound. Abscesses may burst and infect the whole peritoneal cavity. The common causes of widespread peritonitis are discussed elsewhere in this chapter and include perforation of (a) appendix, (b) peptic

ulcer, (c) small intestine, (d) colon and (e) biliary tract, and infection from (a) gangrenous bowel, (b) salpingitis, (c) upper urinary tract infection, and (d) rupture of an hepatic abscess.

The symptoms vary according to the region and extent of peritoneum involved, the nature of the infective agent, and the rapidity of the onset. As described in connection with peritonitis complicating other acute abdominal conditions, there are the following symptoms and signs: abdominal pain, nausea, vomiting, abdominal rigidity, distention, paralytic ileus, toxemia, hyperesthesia, fever, tachycardia, and collapse when there is extensive involvement.

Acute peritonitis must be differentiated from the *colic*, *intestinal obstruction*, *internal hemorrhage*, and *pleurisy*. The differentiation is discussed elsewhere in this chapter.

FEMALE GENERATIVE ORGANS

Ruptured Graafian Follicle

If hemorrhage from a ruptured graafian follicle is severe, the findings may resemble those of ruptured ectopic pregnancy or pelvic appendicitis. It typically occurs midway between the menstrual periods.

Ruptured Ectopic Pregnancy

Ectopic gestation commonly ruptures, leading to slow or rapid, massive intraperitoneal hemorrhage. The history will reveal the presence of *amenorrhea* for 1-2 months, perhaps *morning sickness* and *uterine bleeding*, and, rarely, the *passage of a membrane per vaginam*. In addition to *amenorrhea*, other signs of *early pregnancy*, such as *engorgement of the breasts*, are present. There is *abdominal pain*, chiefly in the hypogastrium and lower quadrants of the abdomen, together with *tenderness*. Before rupture occurs, bimanual pelvic examination may reveal the presence of a *tender, movable mass* beside the uterus, as well as some *uterine enlargement* and *softening of the cervix*. The diagnosis should be suspected in every case of lower abdominal pain in a woman of child-bearing age. Before rupture occurs the condition must be distinguished from *appendicitis*, *threatened uterine abortion*, *salpingitis*, and *ovarian or broad ligament cyst*.

When rupture of an ectopic pregnancy takes place, there is a sudden lower abdominal pain, immediate vomiting, signs of severe hemorrhagic shock, a tender swollen abdomen, and free fluid in the peritoneal cavity. The pouch of Douglas is tender on palpation, the cervix may feel soft, and the uterus is enlarged.

This condition must be differentiated from perforated peptic ulcer or gall bladder, intestinal obstruction, pancreatitis, perforated appendix, torsion of an ovarian cyst, and severe hemorrhage from a graafian follicle. The history and signs indicative of massive hemorrhage, together with other features mentioned above, make the diagnosis of ruptured ectopic pregnancy certain.

The hemorrhage is occasionally small and repeated, leading to the formation of a pelvic hematocoele, with no period of hemorrhagic shock. The pelvic hematocoele is evidenced by fullness of the hypogastrium, it is palpable by manual pelvic examination, and pressure on it causes pain. It may cause urinary retention or frequency.

Twisted Ovarian Cyst

Torsion of the pedicle of an ovarian cyst produces acute abdominal symptoms. The principal features are lower abdominal pain, vomiting, and a tender swelling in the lower abdomen. The onset of the vomiting coincides with that of the pain. There is a rounded, tender mass palpable in the pelvis. Signs of peritonitis appear as time passes and rigidity may then prevent palpation of the mass through the abdominal wall.

This condition must be distinguished from pelvic appendicitis and salpingitis, especially in its early stages, and from pelvic peritonitis of any origin in its later stages. The onset, however, is very abrupt and characteristic. The true nature of the condition may not be determined before exploration of the abdomen is carried out.

Pelvic Inflammatory Disease

This term embraces all forms of infective lesions of the female pelvic organs, but acute salpingitis is by far the most important and common one. There is a history of recent gonorrheal infection, abortion, curettage, or delivery. The signs and symptoms of acute

pelvic peritonitis are present, including lower abdominal pain, nausea, vomiting, and moderately high fever. Tenderness is present over the lower abdomen, and there are varying degrees of rigidity and distention. Purulent vaginal discharge is usually present and vaginal examination reveals bilateral tenderness in the pelvis. Smears of the discharge will contain gonococci if the cause is gonorrhea.

Appendicitis may be confused with acute salpingitis but may be differentiated by the characteristic time sequence of symptoms of appendicitis combined with restriction of pain to the right side. The patient with peritonitis due to appendicitis characteristically appears more seriously ill than the patient with peritonitis due to acute salpingitis of gonorrheal origin. At times salpingitis cannot be distinguished from appendicitis before operation.

Ruptured Ovarian Cyst

The symptoms and differential diagnosis are similar to those of ruptured graafian follicle, but the former may be more severe. Disappearance of a previously palpable ovarian swelling is helpful in the diagnosis.

Retroplacental Hemorrhage

This may occur during the third trimester of pregnancy and cause considerable abdominal distress. On examination, the uterus is greatly distended and tense, pain and tenderness are acute, and shock occurs. An associated toxemia of pregnancy or a history of local trauma may be present. The fetal heart sounds are absent. The history and findings make the diagnosis certain.

Rupture of Pregnant Uterus

This usually occurs near term or during labor. Spontaneous rupture through a cesarean section scar is common. Obstruction of labor may lead to rupture of the lower uterine segment if not promptly treated. Rupture may be caused by external violence or by obstetric maneuvers. If the patient is in labor, uterine contractions cease and abdominal pain and tenderness rapidly develop. Hemorrhagic shock appears, the fetal parts are palpable within the abdomen but outside the uterine wall, and the fetal heart sounds usually stop.

Abdominal Pregnancy at Term

An extrauterine pregnancy occasionally survives well into the third trimester or until term, and abdominal pain and discomfort become very distressing. The diagnosis may be made by palpation of the uterus separate from the bulk of the fetus and its placenta and membranes and by inability to perform successful version to improve the position and lie of the fetus. The diagnosis becomes certain when cesarean section is performed.

GENTOURINARY SYSTEM

Calculus

Small calculi produce attacks of acute renal or ureteral colic as they pass down toward the bladder. The pain begins in the lumbar region on the affected side, is sudden in onset, is colicky in nature, and passes down along the course of the ureter. It may radiate into the external genitalia or medial side of the corresponding thigh. The pain may be severe enough to cause collapse. There is rigidity and tenderness of the abdominal muscles over the course of the affected ureter. The urine may contain only scattered red blood cells or may be grossly smoky or bloody in appearance. An x-ray film usually reveals a shadow of the stone or stones since 95% of calculi are radiopaque. Intravenous pyelography or retrograde pyelography will confirm the diagnosis in doubtful cases. The typical history and findings serve to differentiate renal colic from *biliary colic*, *cholecystitis*, and *acute appendicitis*.

Perinephric Abscess

This is nearly always caused by rupture of a cortical abscess of the kidney which, in turn, is often metastatic from a distant abscess, e.g., furuncle. The symptoms include *pain* over the renal region, *fullness* in the lumbar region, *fever*, *chills*, and often *prostration*. A large abscess is palpable as a tender mass in the loin and downward along the psoas muscle. When well developed the mass is fluctuant. *Röntgenographic examination is diagnostic*: the lumbar spine is curved away from the affected side, the psoas muscle shadow is obliterated, a soft tissue shadow may be present, and the

diaphragm may be immobile. In addition, an intravenous pyelogram may show fixation of the kidney, or displacement of the kidney anteriorly, with distortion of a calyx.

The diagnosis presents no problem when the possibility is entertained, but perinephric abscess may require differentiation from *hepatic abscess* or *subphrenic abscess*. The history, physical findings, and x-ray signs clarify the diagnosis.

Rupture of Kidney or Bladder

Rupture of the kidney is caused by external violence, crushing injury, or penetrating wounds. If death from massive hemorrhage does not ensue promptly, the diagnosis is made from the history of injury, a degree of hemorrhagic shock, hematuria (gross or microscopic), local tenderness and rigidity, and, at times, a palpable mass. Renal rupture may be associated with injuries of other viscera, such as the liver or spleen, but such hematuria is pathognomonic of renal injury irrespective of other lesions. An intravenous pyelogram is diagnostic.

Rupture of the bladder is usually due to external violence when the bladder is distended and is often caused by spicules of bone in cases of fractured pelvis. A history of a crushing injury, a fall, or a blow in the region of the bladder should suggest the possibility of ruptured bladder to the examiner. The test may be intraperitoneal or extraperitoneal, but both produce an acute abdominal condition. Blood and urine escape into the peritoneal cavity or retroperitoneal tissues, causing acute generalized peritonitis in the former and extraperitoneal cellulitis in the latter. Lower abdominal pain, chills, fever, and local tenderness appear promptly, but signs of peritonitis, in intraperitoneal rupture, may be masked for a time by severe shock produced by the injury, e.g., crushed pelvis.

The diagnosis can be made by a consideration of the history, state of shock, and local symptoms and signs. The patient is unable to void properly, there is escape of some bloody urine from the urethra, and an intravenous pyelogram or a cystogram will show extravasation of the dye. Associated visceral injuries must not be overlooked, e.g., rupture of rectum.

Torsion of Ectopic Testis

Torsion of an incompletely descended testis causes extreme sickening pain, usually in the inguinal region. Vomiting and shock may be severe. Absence of the testis from the scrotum on the affected side and a tender mass in the inguinal region confirm the diagnosis.

Acute Pyelitis

This is characterized by pain and severe tenderness over the kidney, high, spiking fever, severe chills, marked leukocytosis, dysuria, frequency, and pyuria. There is usually general malaise and, occasionally, nausea and vomiting. Abdominal pain and associated paralytic ileus, with or without a diffuse mass in the corresponding upper quadrant of the abdomen, may be misleading features, but a careful consideration of the history, physical findings, and urinalysis will clarify the diagnosis.

Urinary Retention

Retention of urine in the urinary bladder causes acute lower abdominal pain, and the distended bladder becomes evident as a rounded, tender suprapubic mass. The history, the mass, and the relief afforded by catheterization confirm the diagnosis.

VASCULAR SYSTEM

Mesenteric Vascular Occlusion

Mesenteric arterial embolism or venous thrombosis is an acute abdominal condition with a grave prognosis, but early diagnosis and treatment may permit a successful embolectomy in the former or lifesaving bowel resection in the latter. The symptoms and signs may be indistinguishable from those of strangulation of bowel with paralytic ileus. In both instances serious changes in the bowel wall quickly develop. However, in mesenteric vascular occlusion, *distention* appears very early. The affected gut occasionally forms a palpable mass. A history of endocarditis or the presence of auricular fibrillation may suggest the likelihood of embolism. Previous thrombotic episodes favor *mesenteric thrombosis*. An enema may demonstrate *bloody bowel contents* which have been carried out

of the lower end of the affected segment of intestine. *Peritonitis* gradually develops and is generalized.

It may be impossible to differentiate this condition in its later stages from *advanced peritonitis* of other origin or from mechanical bowel obstruction in its later stages.

Arterial Occlusion

Occlusion of the aorta or common iliac artery by embolism or thrombosis may cause acute abdominal symptoms, but the diagnosis is rarely in doubt. There is a sudden onset of pain in the lower limb, or limbs, whose arterial supply is suddenly diminished, and loss of the femoral pulse. Acute lower extremity pain, with numbness and paresis, develops rapidly, the severity depending upon the degree of ischemia present, along with blanching and then mottled bluish discoloration of the skin.

Dissecting Aortic Aneurysm

This serious condition produces excruciating abdominal pain, profound shock, abdominal distention, and some abdominal rigidity. The collapse persists, as does the severe abdominal pain, and the femoral pulse may be absent on one or both sides. Back pain is agonizing and persistent.

At its onset, dissecting aortic aneurysm may be confused with *perforated ulcer* or *acute hemorrhagic pancreatitis*. The history, persistent collapse, loss of femoral pulse, and absence of pneumoperitoneum differentiate it from perforated ulcer, and the normal or only slightly elevated serum amylase will aid in the differentiation from acute pancreatitis.

Dissecting aortic aneurysm frequently involves the renal arteries, causing infarction of both kidneys, hematuria, and symptoms of renal colic. Anuria is produced when the renal circulation is completely obstructed.

Ruptured Abdominal Aneurysm

Rupture of an aneurysm of the abdominal aorta, the splenic artery, or some other abdominal artery may rarely occur. Such a rupture is usually quickly fatal, but if the hemorrhage is not too rapid there may be sufficient

time for diagnosis and treatment. The signs and symptoms are those of massive intra-abdominal hemorrhage and free fluid in the peritoneal cavity or an enlarging retroperitoneal mass (hematoma). A history of the presence of an aneurysm and x-ray films demonstrating the outline of the sac or displacement of organs are helpful in the diagnosis.

Pylephlebitis

This may follow a suppurative process anywhere within the abdomen and is characterized by septicemia with high, spiking fever and severe chills. As hepatic involvement develops, right upper quadrant pain, an enlarged tender liver, and jaundice make their appearance. If the splenic vein is involved, splenomegaly also appears. Examination reveals signs of lower right pulmonary irritation and a raised immobile right hemidiaphragm, which can be confirmed by x-ray examination.

Pylephlebitis must be distinguished from *acute nonsuppurative hepatitis* and *liver abscess*. This may be difficult, but the history is usually helpful and the symptoms of pylephlebitis are much more severe.

LYMPHATIC SYSTEM

Acute Mesenteric Lymphadenitis

This condition is common in children and young adults and is manifested by pain, tenderness, and rigidity in the right lower quadrant of the abdomen, usually associated with nausea and vomiting. Fever and leukocytosis are variable. Occasionally a mass, due to enlarged mesenteric lymph nodes, is palpable in the right lower abdomen over the root of the mesentery.

Acute mesenteric lymphadenitis cannot be differentiated from *acute appendicitis* in most cases. The differentiation is only academic because the treatment of the two conditions is the same.

MISCELLANEOUS CONDITIONS

Penetrating and Perforating Wounds

Such wounds of the abdomen may be diagnosed by the history and presence of the wound. Wounds of entry distant from the

abdomen may confuse the examiner if he does not take into account the possibility of penetration of the abdomen. Signs of hemorrhage, peritonitis, and pneumoperitoneum are all of importance, indicating the necessity of immediate treatment.

Indirect and Blunt Trauma

Blunt injury of the abdomen can be diagnosed from the history and by examination which reveals evidence of visceral damage. When doubt exists, early laparotomy is indicated.

Wound Dehiscence and Evisceration

Postoperative abdominal wound disruption with partial evisceration is easily diagnosed by inspection of the wound. One or more coils of intestine usually protrude from the wound.

Wound dehiscence occurs most commonly in patients with malnutrition and malignant neoplasms. Frequently there has been postoperative peritonitis and paralytic ileus with abdominal distention. Violent muscular efforts associated with vomiting and coughing are often precipitating factors.

Wound dehiscence without separation of the skin wound usually occurs 7-10 days after operation. It should be suspected when ileus is persistent or develops without other signs of bacterial peritonitis. An almost pathognomonic sign is the escape of serosanguineous fluid from the wound, along a drainage tract or between skin sutures. If the dehiscence is of sufficient size, extruded loops of gut will be palpable under the skin and will produce a visible swelling. Wound abscess should be differentiated from dehiscence, but they may coexist.

Retroperitoneal Hemorrhage

This may be caused by trauma, breakdown of a retroperitoneal sarcoma, or a dissecting or ruptured aortic aneurysm. Blood behind the posterior peritoneum and infiltrating between the leaves of the mesentery causes abdominal pain, severe back pain, nausea, vomiting, and paralytic ileus. If blood loss is great, hemorrhagic shock ensues. Deep tenderness on abdominal examination is a usual finding.

Hematoma in Rectus Abdominis Sheath

A tear of the rectus abdominis muscle almost always occurs in the lower portion, producing a very tender, tense mass at this site. Most of the cases are seen in women during the third trimester of pregnancy, and there is usually a history of a blow to the abdomen. The mass is vertically elongated if the blood is confined by the rectus sheath. Aspiration of dark blood from the rectus sheath aids in the diagnosis.

Postoperative Intra-abdominal Hemorrhage

If massive hemorrhage occurs, shock and abdominal distention are produced. Pain may be severe, especially at the site of the wound. Early arrest of hemorrhage is essential. This complication must always be seriously considered when progressive shock appears early or late in the postoperative period. The history of events during the operation or the oozing of blood from the wound may help to confirm the diagnosis.

Acute Torsion of the Greater Omentum or an Appendix Epiploica

These have been mentioned in the differential diagnosis of acute appendicitis.

Ruptured Diaphragm

This is caused by violent direct or indirect trauma, often of a crushing type. The signs are those of the presence of abdominal viscera in the thorax, displacing the lung and heart. The diagnosis is confirmed by x-ray examination. Collapse may be profound, owing to severe trauma, associated injuries, and hemorrhage.

CONDITIONS WHICH MAY SIMULATE ACUTE ABDOMINAL CONDITIONS

Pneumonia With Pleurisy

This may simulate an acute abdominal condition by causing *severe epigastric pain* and *abdominal rigidity*. Pulmonary and pleural signs, with a raised temperature, pulse rate,

and respiratory rate, permit a correct diagnosis. True abdominal tenderness does not occur.

Coronary Occlusion

Severe coronary occlusion, accompanied by *shock, collapse, and epigastric pain*, may simulate an acute abdominal condition. At times *paralytic ileus* may develop, but it is rarely persistent. The history, absence of signs of peritonitis, heart signs, constricting chest pain, left arm pain, and pulse irregularities serve to differentiate acute coronary occlusion from abdominal conditions. Typical electrocardiographic changes are confirmatory.

Diabetic Acidosis

Abdominal pain and vomiting may occur in severe diabetic acidosis. *Some tenderness and rigidity* of the abdominal wall may occur. Glycosuria, acetone odor of the breath, deep sighing respirations, diminished serum bicarbonate concentration and elevated blood sugar level, and a history of diabetes mellitus permit differentiation from abdominal conditions. It must be realized, however, that acidosis may be precipitated by an infective intra-abdominal lesion, so that the latter must be carefully excluded.

Periarteritis Nodosa

This generalized disease produces signs of infection with fever, prostration, sweating, loss of weight, and eosinophilia. Abdominal symptoms may closely resemble those of acute ulcerative enterocolitis. Pronounced *abdominal pain, severe intestinal colic, nausea, vomiting, and melena* often occur. Other signs include those of acute cardiac or renal failure and peripheral neuropathy. Acutely painful areas are found in the skin and subcutaneous tissues. The diagnosis is often very difficult but can be made by microscopic examination of a subcutaneous nodule or the appendix.

Tabes

Gastric crises of tabes dorsalis are becoming relatively rare. *Extreme abdominal pain with copious vomiting* occurs in a crisis, but the abdominal rigidity disappears between the pains. Neurologic examination will reveal ab-

normal pupillary reactions and tendon reflexes. A gastric crisis must be differentiated from perforated ulcer

rigidity, and the vomitus does not become feculent.

Acute Leukemia

Acute leukemia may cause rapid enlargement of the spleen with tenderness and rigidity in the left hypochondrium. The white blood cell count and differential count provide the key to the diagnosis as well as generalized lymph node enlargement.

Lead Poisoning

Lead colic of the small intestine is accompanied by constipation. The pain may be severe enough to produce shock. Rigidity of the abdominal wall appears only during the spasms of pain. The history of exposure to lead and a lead line on the gums are usually present. These features and the hematologic finding of stippling of the erythrocytes permit differentiation from other forms of colic.

Herpes Zoster

Herpes zoster involving the lower thoracic nerves gives rise to severe abdominal pain and reflex muscle contraction, the origin of which may be obscure before the skin rash appears. However, the pain is burning in character, and there is associated hyperesthesia. No peritoneal irritation is present, and the pain of unilateral herpes does not cross the midline.

Influenza

This may give rise to abdominal pain of moderate severity but can be differentiated from abdominal conditions by the history and by the presence of an upper respiratory infection. There are generalized muscular aches and pains but little or no abdominal rigidity. Fever is present from the beginning, and malaise is pronounced.

Typhoid Fever

This is discussed in the differential diagnosis of acute appendicitis.

Food Poisoning and Acute Gastroenteritis

The acute symptoms of staphylococcal food poisoning may simulate those of acute abdominal disease. Abdominal pain, severe malaise, vomiting, and collapse, with or without cramps and diarrhea, are frequently noted. The history may reveal the nature of the offending food, and other individuals may be similarly affected. There is no abdominal

Tuberculous Peritonitis

Tuberculous peritonitis is not often an acute condition, but it may cause rather acute abdominal distention, pain, and ascites. There is little or no abdominal tenderness or rigidity, and tuberculosis elsewhere in the body will suggest the diagnosis. The abdomen has, typically, a doughlike consistency, and a mass of rolled-up omentum may be palpable.

ACUTE ABDOMINAL CONDITIONS OF INFANCY

(See also Chapter 30)

There are several acute abdominal conditions peculiar to the neonatal period which have not been mentioned previously in this chapter. All of these acute conditions require immediate or early surgical relief. They are of congenital origin and may be listed as follows:

1 Lesions causing acute intestinal obstruction

- a. Atresia of intestine or colon
- b. Meconium ileus
- c. Annular pancreas
- d. Duplication of alimentary tract
- e. Congenital obstructive band
- f. Imperforate anus
- g. Volvulus of intestine

2 Omphalocele

An obstructive lesion of the intestine or colon is diagnosed by consideration of the history, physical examination, and x-ray findings. Imperforate anus can be diagnosed by inspection and digital rectal examination. The other obstructive lesions listed are not always identified preoperatively, but their sites can usually be determined with the aid of x-ray studies.

Vomiting of feedings and abdominal distention always occur in intestinal obstruction. If the infant vomits greenish material and exhibits visible peristalsis in the upper abdomen, together with dilatation of the stomach, it is likely that there is atresia of the duodenum or upper jejunum, meconium ileus, or annular pancreas obstructing the duodenum. If absence of vernix cells in the rectal contents can be demonstrated by means of the Farber test, the presence of complete obstruction is confirmed. X-ray films of the abdomen, with the infant held in various positions, will demonstrate dilated, gas-filled bowel and the point beyond which the gas cannot pass.

An *omphalocele* may be small or large and can be diagnosed by inspection. A defect in the abdominal wall is evident at the umbilical region, and coils of bowel can be seen through the semitransparent, thinned-out membrane. Immediate operation is the only hope of saving the life of the infant because drying and rupture of the membrane will lead to evisceration, contamination, and fatal peritonitis.

Congenital hypertrophic pyloric stenosis is a subacute abdominal condition which may develop in a young infant, and its description may be found in Chapter 30.

FINAL COMMENTS

An acute abdominal condition presents one of the most fascinating and complex problems in surgery. Decisions concerning treatment must frequently be made promptly on the basis of less evidence than might be obtained if more time for observation and investigation were available. The surgeon must decide whether an operation should be carried out immediately or deferred for a period of time, and, if so, for how long. Certain diagnostic steps should be taken immediately; these have been described in detail near the beginning of this chapter.

Diagnosis of an acute abdominal condition involves consideration of so many possibilities that it is wise first to consider the more common conditions. Less than 20 acute conditions are of common occurrence, although more than 70 have been discussed in this chapter. The vast majority of cases can be included in the following abbreviated list.

COMMON CONDITIONS REQUIRING IMMEDIATE OR EARLY TREATMENT

Operative Treatment

1. Acute appendicitis
2. Acute cholecystitis
3. Intestinal obstruction
4. Perforated viscus
5. Massive hemorrhage
6. Strangulated hernia
7. Ruptured ectopic pregnancy
8. Twisted ovarian cyst

Nonoperative Treatment

1. Paralytic ileus
2. Acute pancreatitis
3. Renal colic
4. Urinary retention
5. Acute hepatitis
6. Biliary colic
7. Acute gastroenteritis
8. Pelvic inflammatory disease

It should be realized that it is better to recognize an acute surgical condition of the abdomen and to act promptly than to wait for further information of a more confirmatory nature in the later stages of the disease and operate either too late to do good or under circumstances less favorable for recovery (Lichtenstein). However, the surgeon who opens the abdomen should be capable of dealing with any condition he may find there.

Peripheral Vascular Diseases

Josephus C. Luke, MD

CONGENITAL VASCULAR ANOMALIES

1. Hemangioma
2. Congenital arteriovenous fistula
3. Glomus tumor

Hemangioma

This group of tumors consists of an actual new formation of blood vessels, probably arising from isolated elements of the vascular mesenchyma which have not been included in the formation of the normal vascular tree. The evidence for this theory is the relative frequency of circumscribed angiomas, with one to three entering arteries and an equally small number of efferent channels. The extensiveness of the hemangioma is probably an indication of its date of commencement, the small ones commencing toward the end of fetal life, while the extensive ones involving superficial and deep tissues arise early in the development of the embryo. The tumor usually continues to enlarge until growth ceases, but in those where arteriovenous connections are present, such as the cirroid type, the increase in size is continuous. Pregnancy and the onset of menstruation may result in an increase in the rate of growth.

Most of the hemangiomas are present at birth and most of the remainder appear in early childhood. It is the commonest tumor of infancy and childhood and, for some unknown reason, is twice as common in females as in males.

Capillary Hemangioma

In this group are several varieties which have acquired different names, but all are similar in respect to their congenital origin and the fact that they occur in various surfaces, chiefly the skin and mucous membranes. The blood vessels are capillary in type, lined by a single layer of endothelium, and sparsely filled with blood.

Port-Wine Stain.—This deforming manifestation of a capillary hemangioma appears at birth and grows with the development of the child. The condition involves the derma and exhibits diffuse telangiectasia but no tumorous enlargement. With years, the color tends to change from a pink to a bluish purple hue. The face and oral cavity are most frequently involved, but the trunk and limbs are also commonly affected.

Treatment is difficult, and no one method is likely to give a good result. The abrasive method of Jonsson is probably the best available. In this, the involved area is rubbed with sandpaper to destroy the cutis and the capillary dilatations. Care must be taken to leave part of the derma, as scarring will otherwise result. Novocain with Adrenalin is used as the anesthetic to produce insensitivity and reduce hemorrhage. A moderately large area can be treated in one sitting. Tattooing of the abnormal area is also used, employing a mixture of pigments to produce as normal a skin color as possible. Only small areas can be dealt with at one time and, consequently, treatment may

to explain the rather rare condition of congenital arteriovenous fistula (usually multiple) in which direct communications exist between otherwise normal arteries and veins. Various varieties occur, the localized ones resembling the cavernous hemangiomas and the generalized variety revealing their presence by generalized changes in the extremity.

Localizing Types.—The terms *cirroid* and *racemose aneurysms* are used in this variety, the latter applying to those in the neck (see above). The points of differentiation from

a cavernous hemangioma are the greater extent of the lesion, more rapid progression, the pulsatile character, and the presence of a bruit over the lesion. Frequently in association are other vascular anomalies and abnormalities such as capillary hemangiomas and marked engorgement of superficial veins.

Generalized Types.—As mentioned previously, the extremities are most commonly involved in this variety, and the diagnosis is made by the recognition of the effects of these vascular communications. Varicose veins, due

Fig. 472—Arteriogram of Fig. 471 showing the dilated and tortuous radial and ulnar arteries and the multiple arteriovenous communications in the palm and 4th finger

Fig. 473—Congenital arteriovenous fistula involving the sole of the foot, associated with changes in the leg due to marked venous stasis

Fig. 474—Arteriogram of Fig. 473

to increased venous pressure, are almost invariably present, coming on early in life and being gradually progressive. Consequently in a young patient with severe varicose veins, the condition should be especially suspected. The complications of these veins, such as ulceration and eczema, may first bring the patient to medical attention. There is an associated enlargement of the limb because of the venous engorgement, increased length of the leg because of epiphyseal vascular stimulation, and increased warmth. Increased sweating and growth of hair are also commonly seen. Various types of surface hemangioma may be associated. A bruit or thrill is rarely present due to the small size of the fistulas.

Laboratory aids in arriving at a diagnosis are the finding of increased oxygen values in the venous blood and arteriography which indicate the multiple intercommunications. Treatment is unsatisfactory due to the numerous small fistulas making impossible their interruption. Excision or stripping of the dilated superficial venous channels is indicated, especially where complications as the result of these veins are present. Compression bandages or a strong elastic stocking, to give an increased tissue tension inhibiting the arteriovenous shunt, should be worn continuously. A scrupulous search with a stethoscope should be made over the area to determine points of localized bruits. Such a bruit indicates a collection of large arteriovenous shunts which, being localized, are capable of surgical excision.

Glomus Tumor

Glomus tumors are not definitely congenital in origin but are included in this group for convenience in classification. The glomus body is a specialized arteriovenous communication which develops shortly after birth and which has the function of local and general heat regulation and also some connection in the regulation of blood pressure. These glomus bodies are microscopic in size and are most frequently found in the extremities but are also present in other parts of the body. As many as 70 such bodies may be present in one toe. They consist of thickened arteriovenous vascular channels associated with large epithelioid cells which are peculiar to these bodies and are

known as glomus cells. Numerous nonmyelinated nerve fibers are in close association.

Glomus tumors are overgrowths of the glomus body enlarging to macroscopic size. A common situation is beneath the nail, but they are also present in other locations in the extremities. The enlargement is slow and metastases do not take place. Recurrence has occurred following excision, but such a recurrence may be due to the development of a new tumor in a contiguous area.

The diagnosis is not difficult if the condition is kept in mind. They manifest themselves as small pinhead or slightly larger bluish nodules in the skin or beneath a nail. Pain is the predominant symptom. It is neuralgic in type, present in the region of the tumor, and is aggravated by cold or heat. Local pressure on the spot produces severe, excruciating, and lancinating pain to such a degree in some cases that the patient shrinks from the slightest contact. When beneath the nail, erosion of the underlying phalanx may take place by direct pressure of the tumor. Treatment consists of surgical excision.

TRAUMATIC ARTERIAL LESIONS

Arterial Spasm

The smooth muscle of the arterial wall has the property of local contraction of a small segment or, as the result of irritation of a localized area, of producing an arterial spasm of the entire limb. Whether the mechanism of this vessel contraction is the result of local overstretching of the smooth muscle fibers and consequent spasm or whether the injury causes severe sympathetic stimulation is not certain. The fact remains that subsequent to trauma of many kinds, arterial spasm can occur severe enough at times to cause complete ischemia of the limb and subsequent gangrene.

This condition is seen most often in war-time due to the passage of high velocity missiles close to major arteries with momentary lateral stretch of the vessel. It has followed other soft tissue wounds, the reduction of fractures, and various orthopedic operations and has been reported as following the injection of sclerosing fluids in the treatment of varicose veins. All degrees of spasm occur from the minor unimportant transient degrees

to the severe type with resultant gangrene. The condition known as Volkmann's ischemic contracture of the forearm and hand following elbow injuries and fractures is probably due to this mechanism.

The prognosis of the limb in the severe states depends on early recognition of the condition in the acute phase so that gangrene can be forestalled. The color, temperature, and sensation of the hand and foot along with the peripheral pulses should be palpated routinely after every limb operation or injury because the majority of extremities lost from this cause are the result of late recognition. Dressings should be loosened, splints removed, and abnormal stretching of joints released. Antispasmodic drugs such as Priscoline 50 mg doses intravenously are of some value; release of sympathetic tone by procaine block of the appropriate sympathetic chain should be done. Increased body warmth and the correction of anemia and blood volume are also indicated. If conservative treatment fails, then surgical exposure of the affected artery should be done without delay. The spastic vessel will frequently relax on contact with warm saline solution applied to the adventitia or injected under pressure intra-arterially. Procaine solution can also be used similarly. Resection of the spastic segment may be necessary as a last resort with replacement by a vascular graft.

Arterial Contusion

Damage to a segment of arterial wall can be produced by direct violence of the original traumatic agent, by operative trauma, or by damage to the artery by a fractured segment of bone. The result of this trauma is hemorrhage into the arterial wall leading to possible thrombosis because of the intimal damage or secondary hemorrhage from later rupture of the damaged artery. As indicated above, possible widespread arterial spasm may also be associated.

Treatment is only indicated when total ischemia is present or threatened, and it is only when the artery is exposed surgically that the lesion can be differentiated from arterial spasm. Arterectomy of the damaged segment is indicated with replacement by a vascular graft when an artery of major caliber is involved.

Partial Division With False Aneurysm

When a major artery is partially severed, especially if done by a small sharp object such as an ice pick, fragment of a grenade shell, or occasionally a bone spicule, bleeding occurs from the arterial hole into the surrounding tissues but is prevented from escaping to the exterior by the smallness of the missile puncture wound. A deep hematoma develops, with thrombosis and fibrosis of its outer layers, containing fluid blood in its interior which flows to and from the arterial tear. The lesion is also aptly called a pulsating hematoma and is a false aneurysm inasmuch as the cavity has initially no endothelial lining.

Fig. 475—Section of brachial artery removed from case of severe fracture of the humerus showing arterial contusion.

The diagnosis of such a lesion depends on a careful search in all puncture wounds and fractures for the following signs:

1. A pulsating swelling in the region of injury
2. A systolic bruit and thrill over the involved area, the bruit being propagated distally
3. Later evidence of nerve compression by the hematoma which may increase gradually in size

It is only in the most major degrees of arterial puncture and partial division that the distal circulation is impaired.

Initial treatment consists of immobilization of the limb and pressure over the injured part. If the pulsating tumor is not increasing in

size and evidence of progressive nerve pressure is absent, then conservative therapy is indicated for a time because the smaller varieties tend to heal spontaneously. These aneurysms may persist undetected for years but are prone to thrombosis which extends to the major limb artery with consequent gangrene. If persisting beyond 3 months, surgical correction is indicated with removal of the false sac (if possible) and closure of the arterial tear.

is small or if produced by a closed type of injury, then a massive hematoma rapidly collects.

In either instance the distal parts are threatened with gangrene due to partial or complete ischemia, the degree of ischemia paralleling the amount of remaining functioning collateral vessels.

Rapid surgical measures are indicated consisting of replacement of the blood loss and

- 4 delayed pain response to noxious stimuli

Fig 477

When the arterial wall defect is extensive and located in a major artery, then resection of the segment is indicated with replacement by a vascular graft. Resection with end-to-end anastomosis is possible in the smaller sizes, when involving a lesser artery, excision only is indicated.

Complete Division

This type of arterial trauma is the most serious of all, both from its high mortality and high incidence of gangrene of the limb. If the wound is open, death from exsanguination is probable unless rapid first-aid measures are carried out. If the external wound

exposure of the severed artery. Ideally, débridement of the severed arterial ends should be done with end-to-end suture. However, in the majority of cases this is not feasible because of the extent of the arterial damage. The majority of such cases will require ligation of the damaged artery with subsequent all-out efforts to keep the functioning collateral vessels as dilated as possible. This is accomplished by repeated lumbar sympathetic procaine blocks or sympathectomy if the patient's condition will allow. With the rapid improvement in the techniques of vascular surgery, arterial ligation should be replaced by the insertion of a segment of vein or homologous arterial graft to

bridge the defect. With these methods a high incidence of limb salvage will be achieved. The greatest number of these cases are seen during warfare, and it is likely that during World War III, banks of homologous or synthetic arterial grafts will be available to the forward surgeon for this type of case. Reports from the recent Korean conflict indicate that about an 80% salvage rate can be achieved in devitalized limbs with the use of this technique.

Fig. 478.—Femoral arteriogram showing traumatic arteriovenous communication between profunda branch artery and vein

Arteriovenous Fistula

A small sharp object such as a fragment of shell may puncture both the main artery and vein. In such an instance the usual false aneurysm does not occur because the escaping arterial blood flows directly into the vein. Such fistulas rarely close spontaneously and soon become lined by vascular endothelium. Due to

the pouring of arterial blood directly into the venous system through a relatively large opening, marked abnormal physiologic changes result which affect the entire cardiovascular system.

1. An immediate fall in blood pressure which later returns to normal levels, but a permanently lowered diastolic pressure which remains, giving an increased pulse pressure

2. Increase in pulse rate; abruptly slowed by 8-16 beats/minute (depending on the size of the fistula) when the artery is compressed proximal to the fistula—phenomenon known as Branham's sign

3. Increased venous pressure in the veins both distal and proximal to the fistula due to the direct dumping of arterial blood into the vein

4. Increased cardiac output due to increased inflow

5. Gradual increase in total blood volume

6. Gradual dilatation and hypertrophy of the heart which may go on to cardiac failure when the fistula has been present for long periods

7. Rapid development of the arterial collateral circulation in the region of the fistula

Clinical manifestations include a thrill over the fistulous tract with a bruit which is loudest in systole but is also heard in diastole (so-called machinery murmur). Decreased peripheral arterial flow will be evident, depending on the size of the fistula. Diminished distal arterial pulses will be present and the ischemia may be severe enough in the large fistulas that distal gangrene may develop. The size of the extremity is increased, and also elevated surface temperature is present. In later cases, evidence of increased venous pressure will be present in the form of varicose veins, some dependent cyanosis, edema, and possibly the complications of venous stasis (ulceration and eczema). An arteriogram will give the location and size of the fistula.

Treatment to close the fistulous tract is indicated because of the late cardiovascular changes. This should be delayed for more than 2 months to allow the collateral vessels time for maximal dilatation. A preliminary sympathectomy of the involved limb is also useful in

this respect to minimize the dangers of acute arterial ischemia to the distal limb immediately after operation. The surgical operation of choice is repair of the arterial opening so that the continuity of the main artery is preserved. However, this is frequently not feasible and the operation most commonly employed is

ARTERIAL DISEASES

Thromboangiitis Obliterans /

Thromboangiitis obliterans was first described as a definite entity by Leo Buerger in 1908 and so is commonly known as Buerger's disease. It had been previously described but

Fig. 479—Types of operations on arteriovenous fistulas

quadruple ligation, tying the artery and vein both proximal and distal to the fistula with, preferably, excision of the fistulous area. If any doubt exists in respect to adequate distal arterial supply, then grafting of the affected arterial segment is indicated

with little differentiation from the other types of occlusive arterial diseases. Buerger's pathologic studies made him conclude that the condition was a subacute inflammation of the vessels leading to thrombosis with subsequent organization and partial recanalization of the

thrombus. The disease can be defined as a segmental, inflammatory, obliterative disease of the arteries and veins which occurs almost exclusively in young men, involving the extremities and occasionally the viscera. The Jewish race appears more susceptible than the Gentile for reasons which are unknown.

Etiology.—The exact cause of this disease is uncertain. Various theories have appeared but each is incomplete. These include focal infection, an allergic response to unknown stimuli and hence related to periarteritis nodosa and the collagen diseases, and, finally, tobacco. This latter factor is the only one concerning which definite knowledge exists, and it appears to be true that the disease is adversely affected by smoking. The causative factor in tobacco smoke is as yet unknown as it has been shown that demicotinized tobacco is just as harmful as the true product.

The high preponderance of this disease in males suggests also some protective influence in the female. This is possibly the vasodilating effect of the estrogens or some other side effect because experimental evidence has shown that female rats are less likely to get gangrene of the tail and that male rats are protected from the effect of ergotamine injections when given theelin. The unprotected male rat is invariably affected following ergotamine.

Pathology.—The disease varies in intensity in different individuals and may be a slowly progressive one with long periods of quiescence or may be a rapidly fulminating type with rapid progression and early loss of one or more limbs due to gangrene. The disease can be divided into four types according to severity.

- 1 Nonprogressive type in which a good collateral circulation develops and which becomes quiescent after one or two episodes.
- 2 The type presenting sudden major arterial or venous occlusion.
- 3 Slowly progressive type which may eventually lead to gangrene or leave a badly impaired arterial tree.
- 4 Fulminating rapidly progressive type requiring multiple amputations.

Microscopically, one sees a diffusely cellular thrombus blocking the arterial lumen, affecting chiefly the smaller arteries such as the dorsals

pedis, posterior tibial, ulnar, etc. The arterioles and the large arterial trunks are seldom involved. A well-preserved media is present and there is some degree of endothelial proliferation. Fibrosis and lymphocytic infiltration of all coats are present, especially in the adventitia and about the vasa vasorum. The accompanying nerve is frequently involved in this periarterial fibrosis, and the vein can show the same involvement of the wall as is seen in the artery. It appears as if some factor primarily involves the endothelium causing a proliferative and irritative effect which results in exudative changes and thrombosis. It is possible that the fibrosis is a reparative aftereffect. Calcification in the vessel wall is very rare.

Fig. 480—Typical toe gangrene in Buerger's disease

Diagnosis.—It must be emphasized that this disease occurs between the age limits of 15-45 years, and it is very doubtful whether such a diagnosis should be made in a person whose symptoms commenced after the age of 45 years. Frequently a diagnosis of Buerger's

comes narrowed or blocked by atheromas or thrombus formation that symptoms occur from ischemia. The same applies to other more important arteries such as the coronary or cerebral vessels.

Pathology.—The changes in arteriosclerosis are the result of the wear and tear phenomena taking place throughout life. However, in certain individuals and in certain disease states, arteriosclerosis appears to develop earlier than

families to the early development of this condition. An elevated blood cholesterol appears to be an influencing factor, and an increase in certain lipid fractions may also play a part.

Two main pathologic types of arteriosclerosis are seen, the more common being the subintimal degeneration and intimal thickening which goes on to produce atheromatous ulcers projecting into the vessel lumen or which become calcified to form the typical plaque

Fig. 184.—Diabetic arteriosclerotic gangrene involving the right great toe. The trophic ischemic changes in the toes and foot are well shown.

in the majority. Calcified spots in major arteries are not uncommon in the late 30's, and arteriosclerosis appears earlier in individuals with diabetes or other lipoid metabolic upsets such as *xanthoma tuberosum* and *myxedema*. There is an increased incidence in certain

The variety is known as *atherosclerosis*. Fibrosis of the media and adventitia is also associated and the elastic laminae show degeneration. The above changes account for the rigidity and tortuosity which an arteriosclerotic vessel demonstrates. Calcification may

be present not only in the plaques but may also be diffusely laid down in the area between the media and intima. With such changes therefore in all the coats of the vessel, especially the intima, it is not surprising that thrombus formation takes place in the lumen. A second variety of arteriosclerotic change is that frequently seen particularly in the arteries of the extremities. This consists of necrosis and calcification of the media, but without gross intimal change, and again the vessels become transformed into rigid tubes (*Mönckeberg type*).

The important phase in the production of arterial obliteration is the development of a thrombus in the vessel lumen or the occlusion of the vessel by masses of atheromatous material. Frequently the two processes are combined. This is most likely in vessels where atheromatous ulceration is present. Such ulcers are commonly situated in large arteries such as the lower end of the aorta where the volume and force of the blood flow prevent for a long time a complete occlusion. Blockage may occur in smaller vessels where the changes are minimal and no evidence of calcification is seen on x-ray.

Symptoms and Signs in the Extremities.—

It is a fact that the arteries of the upper extremity are rarely involved from the clinical standpoint by arteriosclerosis obliterans, and if one artery does become blocked, the collateral circulation is sufficiently good to prevent distal ischemic changes. Therefore, it is the lower extremities that almost invariably suffer from this disease. The patient seeks medical attention usually because of the sequelae of inadequate arterial inflow to the limb, and it must be emphasized that these symptoms are not typical of arteriosclerosis obliterans alone but are present in arterial ischemia due to any cause. The most important symptom is pain which is of two main types. The first is *rest pain* where malnourished tissue produces a scalding, burning pain, probably the result of ischemic changes in the somatic nerves. This pain is always worse at night when the legs are horizontal, aggravated by elevation of the limb, and relieved by hanging the legs over the side of the bed. Pain is also present in association with gangrenous and ulcerative lesions. The second main va-

riety of pain is the type known as *intermittent claudication*. This is a most exact and diagnostic symptom and, as before mentioned, can occur in any variety of arterial obliterative disease of the limb. Intermittent claudication is a cramplike, squeezing pain occurring most commonly in the calf muscles on exercise. The location of the pain depends on the level of the arterial blockage. It may be felt in the foot when the occlusion is in the region of the

Fig. 485—Technique of palpation of the dorsalis pedis, posterior tibial, and popliteal arteries.

knee, in the calf when the block is in the thigh, or in the lateral thigh when the iliac or common femoral artery is involved. This pain is due to muscle ischemia and therefore is felt only on exercise. Rapid walking, walking uphill, or climbing stairs will initiate the pain sooner than a slow pace on level ground. After a rest of 1-2 minutes, the pain disappears, only to appear again after a similar distance has been covered. The distance a patient can walk before the onset of intermittent claudication is a good index to the severity of the arterial occlusion and may vary from 50 feet in the severe cases to a quarter mile in the milder ones.

Other symptoms of arterial ischemia are coldness of the feet, nonhealing infections or ulcers, and various sensory changes, including a hyperesthesia or a numbness and sensations of pins and needles. Examination shows evidence of varying degrees of trophic ischemic changes in the soft tissues of the foot, such as thinning with shininess and loss of elasticity of the skin, decrease in the amount of subcutaneous tissue and atrophy, brittleness, and slow growth of the nails. Hair growth is poor, and hair may be shed from the affected extremity. Sweat glands atrophy, and the foot appears dry and scaly. Ischemia on elevation occurs because of increased venous return and retarded arterial inflow due to the effect of gravity. In hanging the limb down, rubor appears due to pooling of blood in the capillaries and insufficient force at the arterial end of the loop to keep movement rapid. The rapidity of the development of this rubor and its degree are also good indications of the degree of arterial ischemia. A foot which rapidly develops a deep rubor is one with a severe degree of arterial block. A small area of gangrene or infection may be the first signal of arterial disease. These usually result from trauma of some sort to the foot and point a moral that the arteries of every foot should be examined properly and patency assured before an elective procedure is done on the foot, even to the cutting of an ingrown toenail.

Treatment.—

1. Care of the feet: General measures to prevent minor trauma to the feet will obviate many of the disasters that may occur. The well-known paint advertisement, "save the

surface and you save all," applies her washing is obligatory, as is the use of soft wool socks. The feet should be oiled with lanolin or cold cream every second day. Shoes should be pliable and loose fitting to prevent corns and blisters. Toenails need frequent cutting to prevent digging in at the base, the best method being to cut the nails straight across and to scrape the convex surface of the nail that tends to be ingrown. Fungus infection between the toes should be energetically treated if it develops.

2. Complete bed rest is indicated if gangrene or local infection is present. Active exercises should be carried out to prevent muscle atrophy where prolonged immobility is necessary. Dry dressings only should be used on open areas, and antibiotics are useful where infection is present.

3. Ethyl alcohol is a useful vasoconstrictor agent and is also an aid in analgesia when pain is present. Liberal amounts should be used.

4. Heat should not be applied to the affected part but can be used to good effect if employed to produce a state of general vasodilatation. This is accomplished by hot water baths (110°-115° F.) or a baker to the perineal area, producing a state of general vasodilatation with benefit to the circulation of the legs.

5. Vasodilating drugs have not proved to be of much benefit because of their uncertain and transient effect. It is not reasonable to expect a badly damaged vascular bed such as in advanced arteriosclerosis obliterans can be improved by much vasodilatation. Also it must be remembered that these drugs have a generalized effect which will be major in the lesser involved vessels elsewhere in the body and so can possibly decrease the peripheral blood flow because of their action on the remainder of the body. Many supposed good results of vasodilator drugs are really the result of the adaptive capacity of the vascular system. After a period of months following the partial or complete occlusion of a main vessel, the collateral circulation gradually dilates because of the greater volume of blood forced into it. Peripheral circulation improves and, if any of these drugs were coincidentally given

Fig 486—Technique of lumbar block

Fig 487—Typical skin temperature rises

improvement is credited to it. For example, ligation of the superficial femoral artery in a normal individual results in a loss of pedal pulses for only 1-3 months.

Many vasodilating drugs of variable usefulness are at present on the market. Their popularity is evanescent and it is beyond the scope of this book to discuss each separately. Many more will undoubtedly appear in the near future. Those currently in vogue are nicotinic alcohol, Priscoline, and diergocorine.

that it is not a cure but only a method of improving the circulation to the leg. The resulting degree of improvement will depend upon the existing circulation. In those cases with severely involved vessels, the amelioration would be slight and does not warrant the procedure. The operation is indicated where arteriography has revealed that the arterial lesion is not suitable for the replacement by graft but where a relatively good collateral circulation is demonstrated by a rise in foot

Fig. 488—Technique of lumbar sympathectomy (See continuation on next page)

6 In arteriosclerosis the collateral vessels may still show potential vasodilatation. This can be determined if a rise in skin temperature of the foot follows procaine block of the lumbar sympathetic chain. If such a true rise occurs of over 1°C following these tests, then maximal permanent vasodilatation can be accomplished by the operation of lumbar sympathectomy.

This operation carries a low morbidity and mortality, but the patient should be warned

that it is not a cure but only a method of improving the circulation to the leg. The resulting degree of improvement will depend upon the existing circulation. In those cases with severely involved vessels, the amelioration would be slight and does not warrant the procedure. The operation is indicated where arteriography has revealed that the arterial lesion is not suitable for the replacement by graft but where a relatively good collateral circulation is demonstrated by a rise in foot

7. *Arterial grafts.* One of the dramatic surgical advances of the past 5 years has been

the use of grafts to replace occluded or partially occluded vessels and aneurysms. This advance has been made possible by the widespread use of arteriography, which reveals the exact state of patency of the arterial tree, and by the development of arterial graft banks. The techniques of arterial replacement have advanced to the point where any well-trained surgeon should be capable of performing these procedures.

It is our practice to perform femoral or aortic arteriography on all cases of arteriosclerosis obliterans which show evidence of arterial blockage in the femoral artery or higher. A surprisingly high percentage will show evidence of a segmental occlusion with good or relatively good vessels proximal and distal to the occlusion. It is this group of cases which is suitable for arterial grafting. Segmental occlusions are found even where toe

Fig 489—Femoral arteriogram, with accompanying diagram, showing segmental femoral artery occlusion. This is a suitable case for a by-pass graft to restore normal circulation (From Luke, J C. *Postgrad Med* 22: 10-20, 1957)

Fig. 490.—Femoral arteriogram, with accompanying diagram, showing popliteal artery occlusion. This case was not suitable for grafting, but the patient's intermittent claudication was relieved by lumbar sympathectomy. (From Luke, J. C.: *Surgery* 41: 165-171, 1957.)

or foot gangrene is present, but usually in such cases arteriosclerosis is more advanced than in those with intermittent claudication.

Criteria for Selection of Cases

- 1 Good quality femoral or aortic arteriograms
- 2 Evidence that the arteriosclerotic process is not severely widespread in the arteries under consideration
- 3 Evidence that the outflow distal to the occluded segment is of good caliber
- 4 No major arteriosclerotic manifestations in cerebral, cardiac, or renal areas
- 5 Availability to an arterial bank or, as second choice, the use of plastic cloth prostheses
- 6 Plenty of operating time, a steady hand, and an equable temper

The segmental occlusion has usually been slowly progressive, allowing the development of a relatively good by-passing collateral circulation, and consequently no severe ischemic changes occur in the foot. However, with this

main vessel occlusion, blood flow to the distal muscles on exercise is insufficient, and typical intermittent claudication is present. As mentioned previously, the muscles involved by the claudication will depend on the level of main vessel block. Leriche's name is given to the syndrome in which claudication pain is felt in the low back and buttocks, leg atrophy and weakness are present, and impotence occurs in the male. This results from segmental occlusion of the abdominal aorta below the renals. Blockage of the common iliacs is usually associated. Occlusion can occur at any point from this level distally, the most common site being in the femoral artery commencing at the adductor canal level.

These blocked segments of artery can be treated by two different techniques, *i.e.*, arterial grafting or thromboendarterectomy. The former is more commonly used because of its

Fig 491 —Thrombotic occlusion of the lower aorta and common iliac arteries (Leriche syndrome). Note the patent normal-appearing distal vessels

wider applicability. The grafts employed are chiefly preserved homologous grafts stored in an artery bank. However, plastic cloths woven to appropriate artery size are also used and appear to be just as effective as homografts in major arteries such as the aorta or iliacs. In smaller arteries such as the femoral, the woven grafts appear to have a higher rate of thrombosis. Autogenous veins may be used as grafts but are only suitable for smaller arteries as they are not strong enough to withstand the pressure within the major arteries. Thrombo-

endarterectomy (Fig 496) is a procedure in which the occluding material, including the thickened intima, is removed, with repair of the arteriotomy incision and thus restoration of main vessel flow. This is a better procedure as the end result is the equivalent of an arterial autograft and obviates the disadvantage of placing foreign material in the arterial tree. At the present time thromboendarterectomy is chiefly employed in cases of short segmental occlusion of major vessels and in those where a neglected embolus is present.

Fig 492.—Postoperative aortogram of patient shown in preceding figure. The main vessel continuity has been restored by the operation of thromboendarterectomy.

When grafts are used, the blocked artery can be resected with end-to-end anastomosis between the host artery and the graft. This technique is usually employed where major vessels are involved. Where smaller arteries such as the femoral are occluded, a better method is the end-to-side technique in which the end of the graft is sutured to an opening in the side of the host vessel above and below the involved segment. The occluded segment is not removed, and consequently no collateral

vessels are disturbed. The success rate with this by-passing technique has been much higher than in the older end-to-end methods.

Grafts applied to major arteries are almost invariably successful in restoration of normal blood flow, but where smaller grafts are used a higher rate of thrombosis occurs. In our series of 70 femoral by-pass grafts, the immediate and late failure rate has been about 35%. In the more advanced cases where considerable widespread arteriosclerosis is present

Fig. 193—Aortogram revealing arteriosclerotic occlusion of lower aorta and common iliac arteries. The patent distal main arteries indicate suitability for the operations of thromboendarterectomy or resection and grafting.

Fig 494—Technical steps in end to side anastomosis

with associated gangrene, we have been successful in saving, by grafting, 50% of the limbs which would otherwise have required major amputation. Fig 495 illustrates another use of the by-pass graft which was used to relieve impending gangrene of the right leg in a 72-year-old woman with widespread arteriosclerotic involvement of all the vessels.

The use of arterial grafts in the arteriosclerotic vessel is a palliative procedure. The original disease is not checked and usually

progresses with further occlusions and consequent late failure of the graft or the development of coronary or cerebral manifestations. However, from our follow-up data to the present time, these grafts can function for many years with relief of symptoms. The long-term fate of the plastic and homograft is not known, as it is too early for a final evaluation.

8. Amputations are the eventual result in a relatively large number of cases of arteriosclerosis obliterans due to irreversible ischemia

Fig 495—By-pass homograft inserted from left external iliac to right femoral artery to relieve gangrene of the right foot in an elderly, very arteriosclerotic woman (From Luke, J. C.: *Postgrad Med* 22, 10-20, 1957.)

PERIPHERAL VASCULAR DISEASES

Fig 496—Technical steps in the performance of the operation of thromboendarterectomy (lower aorta and common iliac vessels)

and gangrene. The majority of such amputations are done at the lower thigh level because of the poor distal circulation which mitigates against healing of the operative wound. At the Royal Victoria Hospital from 1936-1946, 141 major amputations were performed of which 101 were done because of the results of arterial disease. Eighty-five were done through the mid or lower third of the thigh, 13 were end-bearing amputations at the level of the knee, and 3 were at the site of election. These figures should not indicate that minor amputations are not employed, healing will take place in many local amputations of toes where the circulation has been properly and previously assessed.

Aneurysms

An *arterial aneurysm* may be defined as a dilated segment of an artery resulting from trauma or disease. It is in direct communication with the main vessel and presents as a pulsating tumor. Two types of aneurysms are recognized, the *saccular* where the enlargement has occurred from one wall of the vessel and the *fusiform* where the entire arterial lumen and walls are diffusely enlarged. A third variety has been labelled as an aneurysm but is not truly so, being more a variety of blood vessel rupture. This is the so-called *dissecting aneurysm*.

Arterial aneurysms are lesions of major importance due to their continuing tendency to gradual enlargement and rupture. The syphilitic aneurysm has the worst prognosis with rupture occurring in about 75% of cases within 3 years from the onset of symptoms. Those of arteriosclerotic origin are more slowly progressive, but most of this variety will enlarge and rupture or thrombose within 10 years. However, many of these individuals will succumb from other manifestations of their disease before these catastrophes take place. Until recently, treatment of these lesions has been mainly conservative, but in the past few years the advances in vascular surgery have included surgical removal with a consequent likelihood of cure.

Etiology.—Prior to adequate antisyphilitic therapy, syphilis was the most frequent cause

of aneurysm formation. Now with this disease being detected early and adequately treated, this variety has shown a marked decrease. Syphilitic aneurysms occur chiefly in the aorta, especially in the aortic arch. They are generally saccular and arise from any area of the aortic arch but are commonest in the ascending portion. Enlargement may occur in any direction, resulting in the symptoms of hoarseness of the voice due to interference with the recurrent laryngeal nerves, tracheal tug due to pressure on the trachea, and pain, the result of mediastinal pressure and encroachment on neighboring bony structures. Bony erosion occurs when continued pressure on the thoracic cage exists and erosion and rupture outside the chest wall has been reported. Syphilitic aneurysms have been reported in lesser arteries, but the majority of these are arteriosclerotic in nature with a positive Wassermann reaction as an incidental finding.

Arteriosclerotic aneurysms are the commonest variety found in countries where proper diagnosis and control of syphilis is present. In this type, the aneurysm is chiefly fusiform in shape, and the peripheral vessels are more commonly involved than the aorta. The popliteal artery is the one chiefly affected, and a pulsating tumor in the popliteal space in an elderly individual is not uncommon. The author has seen three separate aneurysms in a 74-year-old female—one involving the left popliteal, a second involving the left superficial femoral, and a third the right common femoral artery. She was brought to hospital because of rupture of the left superficial femoral mass, which necessitated a high left thigh amputation. A common area for aneurysmal dilatation of the arteriosclerotic type is also in the lower aorta and iliac vessels, but the danger of rupture in this variety is not quite so great as in the peripheral types. Abdominal pain and the palpation of a pulsating mass in the abdomen or the finding of a partially calcified tumor on plain x-ray will lead to a correct diagnosis.

Aortography done on elderly arteriosclerotic patients will frequently reveal small unsuspected aneurysms of the lower aorta and iliac

vessels. A systolic bruit is usually present over the aneurysm.

Mycotic aneurysms are the result of weakening of the blood vessel wall, following continued blood stream infection. These occur chiefly in association with subacute bacterial endocarditis and result in small pea-sized or larger aneurysms, usually involving smaller arteries. This variety is rare but is also prone to rupture. They are rarely diagnosed prior to rupture except in the head where even their small size may produce sufficient neurologic signs and symptoms to necessitate investigation

with confirmation of the diagnosis by cerebral arteriograms.

Dissecting aneurysms result from a weakening of the intimal layer of the arch of the aorta usually just above the aortic valves. They occur on an arteriosclerotic basis, but there have been numerous reports of cases resulting from trauma, especially crushing injuries of the chest of the "steering-wheel" variety. The intimal tear is a clean cut, and blood forces its way between the intima and media and may dissect in this plane along the entire length of the aorta to the bifurcation. When the

Fig 499 —Arteriosclerotic fusiform aneurysm of the abdominal aorta and separate smaller aneurysm of left common iliac

blood penetrates through the media to the adventitia, rupture is imminent, as the latter coat will not contain the pressure for long. The usual termination is rupture into the thorax or into the abdominal cavity. Dissecting aneurysms have been reported to reconnect with the aortic lumen at the lower end, resulting in spontaneous cure but with the development of a "double-barrelled aorta." Just distal to the left subclavian is the common site of origin for the traumatic saccular type. The symptomatology of dissecting aneurysms is protean and depends on the location of the involved area. Their rupture (usually preceded by leakage) presents the picture of an acute thoracic or abdominal emergency. Diagnosis is difficult and is seldom made before death, but there are a few reports of operative survival from repair done in the thoracic aorta.

For a description of traumatic aneurysms see page 945

Treatment.—Conservative therapy of aneurysms is notoriously unsuccessful in attempting to halt the progress of this type of lesion. Syphilis requires treatment by high penicillin dosages, but otherwise little can be done. Surgical extirpation of these arterial weaknesses has been gaining momentum, and at present all varieties of aneurysms have a possibility of surgical cure.

Peripheral aneurysms such as the popliteal may be treated by proximal and distal ligation with excision or obliteration of the sac, provided that the collateral circulation is adequate. However, in the elderly arteriosclerotic patient this fact is difficult to assess, and lumbar sympathectomy is an additional safeguard in this respect. The treatment of choice is excision of the aneurysm with restoration of main vessel continuity by use of an autogenous vein graft or preserved homologous arterial graft.

Aneurysms of the proximal aorta are suitable for surgical excision only when saccular in type. The sac neck is clamped, and sutures are placed before the sac is excised. In this way the aortic continuity is not interrupted. The use of hypotensive drugs reduces the chances of cutting through and facilitates suturing in the descending thoracic

by lateral aortorrhaphy, as mentioned above, or resection and replacement by a suitable homograft. Hypothermia (artificially reduced body temperature) is a great aid in preventing paraplegia, a complication of too long an interruption of the aortic flow. Aneurysms of the lower aorta below the renal vessels should be excised in the suitable case with replacement by a preserved homologous graft or a plastic (orlon) prosthesis. A sufficient number of these have now been done to indicate the safety of this procedure, the mortality being 10-15%. Previous methods of treatment, including internal wiring, external wrappings with dicyl cellophane, cutis grafts, and polyethylene, have not produced worthwhile results. If a dissecting aneurysm can be diagnosed clinically, surgical therapy is also effective in this type. The thoracic aorta is transected and the double barrel arranged to flow into a normal single barrel. (See Plate 53.)

Acute Arterial Occlusion

The two main causes of this sudden and frequently disastrous condition are arterial thrombosis and arterial embolism. The differentiation between them is often difficult, but such a differentiation should be made if possible because surgical removal of an impacted embolus is indicated in the early case of arterial embolism but surgery is rarely effective in acute thrombosis. However, only certain sites of lodgment of emboli need surgery, the most common being the bifurcation of the common femoral artery. Embolism of the upper limb rarely needs surgical removal as the collateral circulation is adequate when the blockage is distal to the axillary artery.

Both acute arterial thrombosis and embolism are of sudden onset, but the latter is the more acute. As a rule, acute pain is experienced in the limb with the rapid development of numbness and semiparesis depending on the degree of ischemia. When total ischemia is present, blanching of the limb is followed by a mottled cyanotic discoloration. The distinctive color changes above findings occur in the and consequently a delay, 1 to 2 hours in diagnosis is not infrequently

Fig 500—Gangrene of the foot subsequent to a neglected iliac embolus

Fig 501—Embolus and tail thrombus removed by the technique of thromboendarterectomy in the case shown in Fig 500

treated, anesthesia develops in the distal part of the limb, gradually progressing centrally. The calf muscles become firm to the touch and tender, with loss of all contractile power, and the rigidity of the powerful ankle flexors gives a plantar flexion of the foot. The distal extremity is cold, and, on palpation, a zone of transition between warm viable tissues and cold ischemic ones can be found. Visual evidence of demarcation is also present in this area. Later frank gangrene of the ischemic parts develops.

The main points of differentiation between acute thrombosis and embolism are that embolism usually has a more sudden onset than

brain. More rarely, a portion of a mural thrombus can be dislodged from an arterial sclerotic plaque in the aorta or from a proximal aneurysm. Such an embolus will progress distally and become arrested at a site, depending on the size of the embolus. Rapid narrowing in size of an artery occurs at the sites of major branches or bifurcation, and emboli become lodged at such points.

Treatment.—The diagnosis of acute arterial occlusion is urgently necessary as is also the determination of the cause of occlusion so that therapy can be instituted before irreversible ischemic changes occur in the limb. The results of treatment vary directly

Fig. 302.—Gross leg gangrene, subsequent to neglected common femoral embolus.

thrombosis. The effect of an embolus lodgment is like a bolt out of the blue versus that of thrombosis which is somewhat more gradual and takes several hours to develop. In the case of embolism, there must be some focus from which an embolus could have originated. The focus is most commonly a mural thrombus in a fibrillating heart (left atrium or atrial appendage) or a similar thrombus which has formed following a recent cardiac infarction from coronary thrombosis. Again, a portion of valve vegetation may be dislodged from a case of bacterial endocarditis. However, in bacterial endocarditis the emboli are small in size and block lesser arteries, producing the typical petechiae of this disease. Such a blockage therefore is not severe in effect except in the

with the length of time the occlusion exists and consequently it is imperative that the medical specialist and general practitioner who first see the patient are impressed with the need for speed. After 6 hours of ischemia there is a sharp decline in the number of legs that can be saved, and gangrene and subsequent amputation is the rule.

When first seen, and, particularly if less than 6 hours from onset, conservative therapy is indicated in both conditions. Priscalone is given in a 50 mg dose intravenously, the patient is transported to hospital, and anticoagulant therapy is begun. The leg is kept cool, and procaine block of the appropriate sympathetic chain is carried out to release the spasm of the remainder of the main vessel and the

collaterals which usually occurs as a result of the acute blockage. If signs of improvement in the distal circulation of the limb do not occur within an hour of this therapy, then embolectomy is indicated in those cases where this diagnosis is beyond question or where reasonable certainty exists that such a diagnosis is correct. The diagnosis of embolism must also include a correct level of lodgment of the embolus. Such an assessment is made by digital palpation of the vessel pulsations, the site of pain and paresthesia, the determination of where the level of ischemia commences, and

thrombus is found occluding a major artery, as, for example, the superficial femoral, and the surgeon is certain that the block is segmental, then the techniques described (pp. 956-962) are indicated. Acute segmental thrombosis producing severe distal ischemic effects, however, is a great rarity, and the usual finding is that the main vessel is thrombosed over a long area. Occasionally this long thrombus can be removed by opening a distal artery such as the popliteal or posterior tibial and flushing the thrombus upward to the femoral arteriotomy opening. The results of this technique are uncertain, especially in the advanced arteriosclerotic patient, and all too commonly major amputation is necessary. In summary, then, one can say that surgery is indicated in a diagnosis of arterial embolus but has little to offer in acute arterial thrombosis.

Certain site of lodgment of emboli or sites of acute thrombosis do not require surgery and will respond well to conservative therapy. The anterior and posterior tibial arteries when blocked will not result in severe ischemia, and the same can be said for the radial and ulnar arteries. Popliteal and brachial embolectomy is also seldom required.

ARTERIAL CONDITIONS SUBSEQUENT TO AUTONOMIC IMBALANCE

Raynaud's Disease and Raynaud's Phenomenon

Under this heading is included a group of closely allied conditions, the result of arteriolar spasm rather than organic occlusion. All the varieties resemble one another but in different degrees. Classic Raynaud's disease consists of attacks of arteriolar spasm, most commonly affecting the hands and rarely the feet. Women preponderate in the ratio of 4 or 5:1. Cold is a precipitating factor in the majority, but emotional stress may also bring on attacks, indicating the fact that the emotionally unstable individual is more prone to this disease than the stable, well-adjusted person. True Raynaud's is differentiated from Raynaud's phenomenon by the fact that the attacks are clear cut, relatively abrupt in origin, and consist of a period of intense vasoconstriction lasting

Fig 303—Frequency of embolus lodgment

the use of the oscillometer. The sites of bifurcation of the main arteries should be kept in mind, as an embolus is most likely to plug an artery where an abrupt change in its lumen results from the sudden giving off of a large branch.

It is frequently difficult to distinguish clinically between acute embolism and thrombosis. An arteriogram can be readily performed and will be of great benefit in giving the correct diagnosis. In a dubious case, if conservative therapy has not shown improvement in the distal circulation, then surgery should be attempted in an effort to save the foot. If a

PERIPHERAL VASCULAR DISEASES

5-20 minutes, when the fingers are white and numb, followed by deep cyanosis and finally a burning erythema of the involved digits. In Raynaud's phenomenon, the same etiology is present but the effects are slightly different. Blanching is not so dramatic and the return to normal color is gradual and does not show the stage of cyanosis or erythema. There is the occasional case where the etiology appears to be due to the use of vibrating tools such as the pneumatic hammer.

In 1933 a cold precipitable globulin in the blood was first described. Since then this work has been confirmed on many occasions, and this variety of globulin has been called *cryoglobulin*. It appears in small quantities in many diseases but is especially marked in multiple myeloma. In other conditions in which no definite disease entity is present, its appearance is labelled as essential cryoglobulinemia, and it manifests itself in many ways, such as cold sensitivity, Raynaud's phenomenon, purpura, and livedo reticularis. Superficial gangrene of the extremities has been reported on four occasions. This abnormal protein precipitates in the blood vessels on exposure to cold, the precipitant acting as a foreign protein with resulting surrounding tissue reaction, thus explaining the many manifestations recorded. This also explains the localized areas of skin necrosis and ulceration, localized gangrene, and localized attacks of Raynaud's phenomenon encountered. Therefore cryoglobulinemia should be suspected in any bizarre case where the manifestations are multiple and resemble those of autonomic imbalance out of the ordinary.

Precipitation of an elastic translucent gel occurs when the patient's serum is exposed to cold and electrophoresis, indicating that cryoglobulin migrates to the gamma globulins. ACTH and cortisone apparently suppress this globulin and produce remission of symptoms either temporarily or, rarely, permanently.

Diagnosis.—The history in such a case is the most important point in establishing a diagnosis. Attacks of blanching of a finger or fingers, gradually increasing in severity and possibly gradually involving more and more of the hand, are characteristic. The presence of the "three-color phase" in such a case is pathognomonic of Raynaud's disease. The

preponderance in women, involvement of both upper extremities, relatively early onset (aged 20-40 years), and the precipitating factors of cold and emotional tension should give a clear diagnosis in the absence of any signs at the time of examination. During an attack (which frequently can be precipitated at will by exposure to cold), varying degrees of blanching are seen from dead white to a yellowish hue. The fingers feel numb and clumsy. The radial pulses are normal so far as palpable pulsations are concerned because the condition is arterial in type. Raynaud's attacks can be initiated by the conditions which produce as cervical rib and scalenus anticus syndrome. Less intense attacks of Raynaud's phenomenon occur also in rheumatoid arthritis and Boeck's sarcoid. Such causes should be ruled out before a diagnosis of idiopathic Raynaud's disease is made.

In the occasional severe case with frequently repeated severe episodes of spasm, organic changes appear in the digital arteries. These consist of thickening of the arterial walls and occasionally thrombosis. In such a case, it is not uncommon for infections to occur about the finger tips, chiefly about the nails. These are chronic and painful and may result in local patches of superficial gangrene.

Scleroderma of the fingers and hand is occasionally seen as a complication to Raynaud's disease. The skin becomes atrophied and tightly stretched, and the deeper tissues are fibrosed even to the joints. Circulation is further decreased by this process, and organic vascular occlusion occurs with resultant trophic changes in the digits. Gangrene and chronic ulceration frequently supervene.

Treatment.—It must be kept in mind that the great majority of cases of Raynaud's disease and Raynaud's phenomenon are mild and therefore the individuals never seek medical advice. They have discovered for themselves that if they protect their hands from cold, wear warm clothing in winter, and avoid handling cold objects, they will be relatively comfortable. The removal to a warm climate in the winter may be necessary. Emotional states are harder to control, but reassurance and careful medical guidance are of benefit. Medical management also includes vasodilator

Fig 504—Diagrammatic illustration of technique of preganglionic upper dorsal sympathectomy

drugs and estrogen therapy because of its vasodilating effects. In the severer cases and especially where organic changes are occurring in the finger tips, surgical treatment is indicated. Preganglionic section of the sympathetic fibers to the arm gives spectacular initial results

According to Smithwick's technique, the upper dorsal sympathetic chain is sectioned below the 3rd thoracic ganglion and the white and gray rami to T2-3 are sectioned, the former being removed intraspinally by intraspinal section of the somatic nerves T2-3. The proximal portion of the sympathetic chain is then removed as far as possible from the field by suture of its free distal end to the muscles of the back.

Results from this operation unfortunately are not permanent, and about 60-70% of cases tend to recur to some degree after 6 months. The reason for this recurrence is not clear; local arterial sensitization to circulating Adrenalin has been cited as a factor. Sensitization of the arterioles to cold or regeneration of the interrupted sympathetic pathways has also been blamed for recurrence

More recently a return to the older surgical technique of removal of the stellate and 1st and 2nd dorsal ganglia has become popular. It has been shown that better long-term sympathetic denervation of the upper limb can be achieved by this method. The only disadvantage to this operation is the production of a Horner's syndrome

Acrocyanosis

Acrocyanosis is a vascular imbalance resulting in a primary loop with peripheral etiology is obscure but associated with the same disturbance. The difference, however, is that the hands and feet feel deep cyanotic blue. The fingers are reddened somewhat but the deeper blue in the nail beds will result in the fingers appearing maroon in color. It is more involved than Raynaud's disease and most frequently occurs in women.

The hands are cold and show the characteristic mottled appearance of other symptoms.

Acrocyanosis, with the muscle show a reversal of the normal into the arms on a he sympathetic men-

veins in-

Investigation of a proper assessment of the affected termination of the competence occurs. Upon question of treatment tests have been de-

Fig 505
on 1

phyton infection may be troublesome due to the excessive sweating of the feet

Treatment.—Treatment is unsatisfactory, and the condition tends to persist although decreasing somewhat with age. Lumbar sympathectomy may be indicated in the severe cases, especially where marked sweating and Epi-dermophyton infection are associated.

Livedo Reticularis

This variety of neurovascular imbalance is characterized by patches of cyanotic reddish mottling on the feet and legs, extending to the knee. The hands are also frequently involved. The vessel changes are similar to acrocyanosis but are patchy and more widespread. The patient may complain only of the appearance, but coldness, clamminess, puffiness, and some numbness may be mentioned.

The majority of patients do not require any specific therapy beyond reassurance and an explanation of their condition. In the rare case where symptoms are more severe, lumbar sympathectomy will provide relief, although the bluish, mottled areas merely turn to pink. However, the coldness, wetness, and puffiness are relieved.

VASOMOTOR CHANGES RESULTING FROM TRAUMA AND INFECTIONS

When tissue is damaged by trauma or an infective process, the resultant healing is dependent to some extent on a normal nervous control of the reparative process. In the occasional rare case there appears to be an abnormal nervous control which may show a preponderance of the vasoconstrictive (sympathetic) tone or, rarely, vasodilator preponderance. The degree of such abnormality varies greatly, and the lesser degrees are transient and pass off before serious effects are noticed. However, in the occasional case, a chronic state of either vasoconstriction or vasodilatation of the vascular bed results. Such a continued effect leads to an abnormal process which has a widespread result in the limb and shows, in the spastic type, clinical evidence of vasoconstriction and coolness of the limb, increased sweating, pain, and vague, poorly defined sensory changes in the limb. The peripheral pulses appear to be reduced, edema

may be present, and the joints become stiff and painful. The vasodilatation type shows a limb which is warm, painful, dry, and edematous, and which later may show a typical spotty decalcification of bone known as Sudeck's atrophy. The pain in both types is typically causalgic in nature, and a case may begin by showing the vasodilatation phase which later (2-3 months) changes over to the vasoconstriction type.

Trauma of a mild degree, such as that resulting in a sprain, may be the initiating factor, and the author has seen cases resulting from burns, minor fractures, and even minor surgical wounds such as an incision for drainage of an abscess. Infections in the limb, such as cellulitis or phlebitis, may be the originating cause. This whole condition is somewhat vague and poorly understood, and the exact nerve pathways taken by these abnormal reflexes is not clearly known. Why one person will be affected and not another from identical trauma is not known, but it appears as though this condition is more likely in those persons who show instability of the nervous system, especially the autonomic portion.

Treatment.—The fact that a neurovascular imbalance is present is utilized in treatment, and interruption of some portion of the reflex arc is logical therapy. The sympathetic supply to the limb is the efferent arc to this reflex, and it is simple to interrupt. Procaine block of the appropriate sympathetic chain will often give dramatic temporary relief of symptoms which lasts for a progressively increasing length of time after each block, and after the second or third the curative effect may be permanent. If a temporary effect only is noted after each block, then a sympathectomy will give a permanent effect. In the later cases where osteoporosis is severe, edema has been present for a long time, and joint stiffness is present, long-continued physiotherapy is a necessity in producing recovery.

DISEASES OF VEINS

Varicose Veins

A varicose vein may be defined as an abnormally dilated vein, and, for practical purposes, the legs and lower abdomen are almost solely involved. These veins show an increase

in caliber, sacculations due to patchy thinning of segments of the vein wall, elongation and tortuosity, and fibrous thickening of other portions of the wall. A loss of valvular function takes place, and at times calcification of the vein wall may occur.

Etiology.—There are two main types of varicose veins from the causative standpoint. The *primary* ones develop in early adult life and probably arise on the basis of a congenital defect in the structure of the vein. This structural defect is hereditary, as a tendency to varicose veins is often seen in certain families. Such a defect is likely a weakness of the wall and valves of the veins. Also a decreased initial number of valves may be present, the normal number being 6-8 in a competently functioning great saphenous vein. This congenital and hereditary background is probably the reason that pregnancy will cause the appearance of varicose veins in one woman and not in another, or why one shopgirl who stands all day will develop varicose veins, whereas another will not.

Secondary varicose veins are those that develop following increased venous pressure acting upon them from the main venous trunks. These follow a *previous* deep phlebitis where increased venous pressure can occur in the damaged deep vein from direct transmission of increased intra-abdominal pressure. This increased pressure is transmitted to the superficial veins and structural defects in the valves and vein walls occur with the development of true varicose veins. Another example of this mechanism is the development of hemorrhoids and esophageal varices in portal hypertension. The rapid development of varicose veins in a middle-aged individual should raise the possibility of the secondary type and can arise from large intra-abdominal tumors, ascites, and cardiac failure.

Signs and Symptoms.—In some cases, well-developed varicose veins result in no symptoms whatsoever, and patients present themselves for treatment from the cosmetic standpoint. However, the usual complaints are those of tiredness, heaviness, fullness, and aching of the leg after prolonged standing and therefore worse toward the close of the day. Menstruation usually aggravates the complaints. Symptoms of uncomplicated varicose veins should

be completely relieved by recumbency, with the possible exception of nocturnal muscle cramps. To give the above symptoms, the veins should be well developed and should show a positive Trendelenburg test (a reversal of flow in the vein when the patient assumes the upright position). Beware of falling into the common error of blaming leg symptoms on a few varicose veins, especially where the symptom complex is at variance with that mentioned above!

Fig. 506.—Extensive primary varicose veins involving both legs

An essential part of the investigation of a case of varicose veins is the proper assessment of the degree of incompetency of the affected veins and valves, and a determination of the level at which the incompetence occurs. Upon this knowledge the entire question of treatment depends. A number of tests have been designed to answer this point, and all are modifications of the original Brodie-Trendelenburg test. This test is done by having the patient in a horizontal position, with the affected leg lifted. The blood drains out of the superficial

veins, assisted by massage centrally with the hand. With the veins collapsed, a rubber tourniquet is placed around the upper thigh sufficiently taut to compress the superficial veins only. The patient stands with the tourniquet on, and the veins below the tourniquet should remain collapsed up to 20 seconds if the communicating veins and small saphenous vein distal to the tourniquet are competent. Release of the tourniquet will now give rapid filling of the distal varices from above when incompetence of the valves of the saphenous vein only is present. If with the tourniquet on the thigh and the patient standing, the distal

varices fill immediately, this indicates an incompetent valvular mechanism between the deep and superficial venous systems below the level of the tourniquet, and the small saphenous vein can be included in this group of communicating veins. The site of the incompetent communicating vein or veins can be determined by repetition of the test using multiple tourniquets placed at different levels or by moving the single tourniquet gradually more distal until a level is found where the distal varices do not immediately fill but only fill when the tourniquet is released. At this level one is therefore just below the point of the most distal incompetent communicating vein.

Treatment.—

Primary Veins.—Where small dilated veins are present with no symptoms and the patient shows no reverse flow in the veins on performing the Brodie-Trendelenburg test, then local injections of a sclerosing fluid are indicated if the patient wishes treatment for cosmetic reasons. When reverse flow occurs in the great saphenous vein alone and there are no incompetent communicating veins, a choice of surgical procedures can be employed. Ligation of the great saphenous vein as close to the femoral junction as possible will interrupt the incompetent vein at its source. The vein can then be obliterated by the injection of sclerosing solutions either at time of operation or subsequently. These solutions must be used with care because of several possible complications. Allergic manifestations are not too rare, especially in those persons who have an allergic tendency. Preoperative testing for sensitivity should be done in all cases before injection. Neglect of this precaution has resulted in many cases of sudden death from anaphylactic shock. Another danger in the use of sclerosing fluids is the fact that when injected into a superficial vein a certain proportion of the fluid inevitably gets into the deep veins. This may occasionally result in deep venous thrombosis with crippling damage to the leg and the occasional case of pulmonary embolism.

Stripping of the great saphenous vein is undoubtedly a better procedure in all cases of incompetent varicose veins, as removal of the diseased vein results in a reduced tendency

Fig. 507.—Pronade venogram in a normal individual. Although patient is erect, the contrast medium ascends in the narrow, straight-walled veins.

to recurrence. Stripping should be the only surgical procedure in those cases that show evidence of incompetent communicating veins because of the high rate of recurrence in cases when the ligation and injection technique is employed.

In about 20% of cases the small saphenous vein shows incompetent valves, and this vein will also need surgical attention. It should be ligated as high in the popliteal fossa as possible and then distally injected or stripped according to the preference of the surgeon.

Varicose veins are not diseased tissue that can be obliterated or removed with any degree of permanency. The student should realize that he is dealing with a gradually progressive condition involving all the superficial (and possibly to some extent the deep) veins of the legs and that removal of one set of veins will not prevent enlargement of remaining ones. Some evidence of new varicose veins following surgery occurs in most cases, but the degree of the recurrence will depend to a great extent on the excellence of the job done

Fig 508—*A*, Retrograde venogram showing the contrast medium descending rapidly in widely dilated varicose veins

B, Lateral view taken 25 seconds later. The contrast medium is now escaping into the deep veins

flow on standing, and therefore a positive Trendelenburg test, then these damaged veins only aggravate the venous stasis and should be corrected.

The method of correction should be by the stripping technique as the use of sclerosing fluids is dangerous due to the already damaged deep circulation. The patient should be warned prior to the operation that this procedure is not totally curative but will improve to some degree the venous stasis in the damaged leg. The instructions necessary for the care of the postphlebotic leg must still be carried out because of the continuing deep vein damage

(See p. 989.) The use of the elastic stocking as outlined will in many cases obviate the need for the surgical correction of these secondary varicose veins.

Complications of Varicose Veins.—Venous stasis, whether from incompetent superficial varicose veins or from deep veins following a previous phlebitis, results in the occurrence of several abnormal physiologic states. Increased venous pressures are present in the upright position and particularly after straining, with elevations up to 400 mm. of water from a normal of 50-100. This allows stasis of the capillary loop, resulting in cyanosis, and

Fig. 510

Fig. 510.—Retrograde venogram of common femoral vein which has been occluded centrally by digital pressure. Valves show excellent competency (patient recumbent).

Fig. 511.

Fig. 511.—Retrograde venogram of superficial femoral vein. Valves which are located at the bulbous dilatations show marked incompetence.

Fig 512—Typical varicose ulcer

also anoxemia of the endothelium allowing increased permeability and edema. This edema together with some decrease in O_2 and increased CO_2 tensions, also occasionally increased NPN values, results in tissue devitalization and paves the way for the complications.

Varicose Ulcer—When ulceration is present in association with varicose veins, these varicosities must be of a relatively severe degree and show valvular incompetence with reversal of flow on standing; otherwise such an ulcer is not a true varicose one. Varicose ulceration is usually preceded by the preliminary changes of chronic venous stasis. This results in brownish skin pigmentation, the result of the deposition of hemosiderin subsequent to the breakdown of extravasated red cells, also thinning of the skin with fibrosis, and devitalization of the underlying fatty tissue. Chronic edema is frequently present, aiding in the development of these changes and encouraging the presence of chronic low-grade periphlebotic infection and consequent induration.

With such devitalizing influences present, it is not uncommon, spontaneously or following a slight trauma, that an ulcer develops which persists as long as the chronic venous stasis is allowed to remain. This ulcer is most commonly located just above the medial malleolus but may be anywhere in the lower half of the leg if trauma has been the initiating cause. Each time the ulcer recurs following inadequate treatment, further fibrosis is added to the former ulcer area, rendering the tissues more devitalized and so more liable to further ulceration.

Treatment consists of correcting the underlying cause of the venous stasis by removal of the varicose veins. The ulcer is treated by some type of compression bandage to remove edema. The best dressing is still Unna's paste boot. Bed rest, hot dressings, and the use of antibiotic drugs will be necessary in the acutely inflamed ulcers.

Fig 513—Hypertensive ulcer showing the indolence and surrounding skin devitalization associated with skin infarction resulting from hypertensive cardiovascular disease.

To many practitioners any chronic leg ulcer is diagnosed as being varicose in origin. This is incorrect in many instances and leads to improper treatment. Many saphenous ligations or strippings have thus been done unnecessarily. The problem of the chronic leg ulcer is badly managed by the profession as a whole, with undue emphasis being placed on local treatment and insufficient thought as to the etiology.

The following list indicates, in order of frequency, the different causes of chronic leg ulcers, and these causes should be kept in mind in determining the correct etiology so that the appropriate therapy may be instituted:

- 1 Varicose ulcer
- 2 Postphlebotic ulcer
- 3 Ischemic (hypertensive) ulcer
- 4 Syphilis (tertiary)
- 5 Tuberculosis (erythema induratum)
- 6 Squamous cell carcinoma
7. Associated with splenic diseases (splenic anemia, Gaucher's, etc.)
- 8 Chronic pernio
9. Blastomycosis and other allied conditions

Varicose Eczema.—Another of the manifestations of chronic venous stasis is that of eczema. This usually consists of a patchy involvement of the medial ankle region but may be severe enough to involve most of the lower leg. It is manifest by a red, exuding, scaly involvement of the skin, and the patient complains of edema, burning, and itching of the affected part. Again, it should be pointed out that, to be true varicose eczema, incompetent varicose veins must be present. A previous deep phlebitis, diabetes, or sensitivity reaction should be ruled out. Treatment consists of support to the leg, the same as for varicose ulceration, plus the correction of the incompetent varicose veins.

Superficial Phlebitis.—Varicose veins are more prone to the development of phlebitis than normally functioning ones because of the relative venous stasis present in addition to the fact that their exposed position renders them more liable to trauma. Such a phlebitis is diagnosed by the signs and symptoms of pain, redness, soreness, and hardness in varicosities previously soft and painless.

Minor degrees of this complication are readily controlled by a pressure bandage such

as Unna's paste boot or elastic adhesive dressing. There is no need for the patient to be immobilized. Major degrees involving a large stretch of vein, especially where extension toward the saphenofemoral junction is taking place, are best treated by high saphenous ligation at the saphenofemoral junction. This has the merit of preventing the rare case where the saphenous thrombus extends into the femoral vein with therefore possible embolus formation; also it corrects the basic fault in the original varicose veins. The inflammatory thrombus present obviates the need for the use of sclerosing fluid, and the same ultimate effects of obliteration of the varices take place. This method of therapy allows the patient to be ambulatory, corrects the underlying venous pathology, and so prevents recurrent attacks. A pressure dressing is applied to the leg after operation to reduce the pain, stiffness, and edema resulting from the phlebitis.

Venous Thrombosis

Thrombosis of blood in the venous tree is a complication fraught with danger to the patient's life and may result in varying degrees of mild to severe disablement. There are three principal factors which result in venous clotting:

1. Increased coagulability of the blood which may follow trauma or be secondary to anemia or polycythemia or may be present for some undetermined reason.
2. Slowing of venous blood flow which may occur secondary to heart disease, dehydration, or prolonged immobility.
3. Damage to the intima of the vein resulting from trauma or infection.

The degree, extent, and type of the venous thrombosis vary according to the degree of associated inflammation and may vary from the bland, quiet phlebothrombosis to the severe septic thrombophlebitis.

Bland Thrombosis (Phlebothrombosis)

When the inflammatory element is mild and the intimal damage is minimal, blood clotting in the vein will take the form of a soft, loosely attached clot which gradually propagates centrally. Such a process most frequently originates in the veins of the lower extremities be-

cause in these veins the above-mentioned factors predisposing to thrombosis are most frequently met. Those of the sole of the foot, the calf, and the adductor region of the thigh are most commonly originally involved. Propagation of the clot from these regions may take place into the main venous channels of the leg and progress centrally even as far as the vena cava.

The thrombus originates as a collection of platelets which adheres to the intimal endothelium at some area where intimal damage from whatever cause has taken place. Leukocytes and fibrin adhere usually in layers, and a white thrombus is formed. Further clotting is mixed with red cells, and a red thrombus is formed which progresses centrally with little or no attachment to the vein wall. Such a loosely adherent or freely floating clot attached only distally is known as a "tail" thrombus and consequently is easily detached to act as an embolus. Such a fragment finds lodgment in the lung to produce the typical pulmonary embolus, and the amount of pulmonary artery occluded will depend directly on the size of the thrombus detached, those from a small distal vein will produce minor emboli and those from a major vein may block the origin of the pulmonary artery, producing sudden death.

Bland thrombosis may originally be associated with only a mild degree of inflammation of the vein wall but such an inflammatory involvement tends to increase in some cases and consequently an original case of phlebothrombosis may progress to a full-blown thrombophlebitis.

Signs and Symptoms.—It must be emphasized that this condition can occur both in medical and surgical diseases but probably is more common after surgery and childbirth. Symptoms may be completely absent, the first indication of the lesion being that of a pulmonary embolus. Many of these emboli are massive and produce the tragic occurrence of sudden death during an apparently uncomplicated convalescence. Signs and symptoms, however, usually occur first in the leg where the majority (95%) of such thromboses originate. Some aching in the foot, the calf, popliteal region or thigh will be noticed by the patient, and the leg will

have the sensation of fullness and stiffness. Such symptoms usually occur or are aggravated when in the upright position (Luke's sign.) Mild fever is present and the pulse is usually slightly elevated. Tenderness in the sole of the foot, the calf, popliteal region, or medial thigh may be found, and slightly increased warmth of these parts is usually present. A sense of fullness of the muscle mass of the calf is a very constant finding. A feeling of tightness or pain in the calf is produced in the majority of cases by forced dorsiflexion of the foot with the knee extended (Homan's sign). Mild edema of the

Fig. 514.—Pronade venogram in a case of phlebothrombosis. The contrast medium flows along the sides of the loosely attached clot, forming a "mantle shadow." This patient had suffered a pulmonary embolism.

ankle and lower leg is present, and the foot may show some cyanosis on dependency. The sedimentation rate is elevated.

It cannot be emphasized too often that the condition of bland thrombosis and that of thrombophlebitis are part of the same process and differ only in the degrees of in-

flammatory involvement. Bland thrombosis has been described as an entity chiefly because of its minimal signs and symptoms and its great tendency to embolize (30% of cases). Consequently, with the possibility of such a serious complication, every effort should be made to prevent this development or to recognize it in its early stages. The condition should be constantly kept in mind and looked for in every postoperative patient, and a serious view taken of even the mildest leg complaint in any patient so that early therapy can be instituted and a possible pulmonary embolus averted.

Fig 315.—Pronade venogram showing occlusion of a major branch of the popliteal vein by phlebotrombosis. Only a small stub remains patent.

Thrombophlebitis

As mentioned above, thrombophlebitis presents the picture of venous clotting associated with marked inflammatory involvement of the vein and, to some degree, the perivenous structures. The same etiologic factors pertain as in bland thrombosis, consequently it may occur following childbirth or a surgical operation, especially where infection is associated.

The incidence is about 2% following surgical operations and is highest in kidney and bladder cases, major gynecology, or such abdominal lesions as a perforated appendix. As in bland thrombosis, it occurs between the 5th-15th postoperative or post-partum day and takes place in the leg veins in the great majority of cases, though primary involvement of the pelvic veins may occur. The veins of the portal system occasionally are affected from some suppurative lesion in the abdomen, but this condition appears to be much less common than formerly due to the improvement in surgical technique and the use of antibiotics. Certain medical diseases show a relatively high incidence of thrombophlebitis of the leg, such as typhoid fever, pneumonia, Buerger's disease, and ulcerative colitis. Occasionally thrombophlebitis is seen where no definite predisposing factor can be determined, but in such cases some infectious process such as an upper respiratory infection has usually preceded the onset. When such a spontaneous thrombophlebitis exists, the possibility of an undiagnosed malignancy in the abdomen should be considered. It has been shown that cancer of the body and tail of the pancreas has associated episodes of leg thrombophlebitis in about 30% of cases.

Signs and Symptoms.—In the acute form, the patient will complain of a relatively sudden onset of a severe ache in the involved leg, variously localized in the calf, popliteal area, or thigh. The temperature climbs to 101°-103° F. Some cyanosis of the leg, even when horizontal, is usually present, and severe edema soon appears involving the lower leg only when the process starts distally or involving the whole leg and buttock when the femoral and iliac veins are affected. Acute tenderness is present over the involved area; the part is hot and full to the touch and pain results from muscular movement.

All gradations of thrombophlebitis occur from the fulminating type of acute massive venous occlusion to the lesser degrees resembling bland thrombosis. Luke's sign also applies to thrombophlebitis and is an early diagnostic indication. A fulminating variety of thrombophlebitis is occasionally seen where the degree of involvement is sudden and severe and is associated with a major extent of arterial

vasospasm to such a degree that the picture of acute arterial thrombosis or arterial embolism may be simulated. However, the leg edema and cyanosis will usually indicate the true picture. The arterial spasm may be of such a degree that true gangrene develops, and such a lesion demands energetic treatment to obviate such a possibility. This consists of high elevation of the leg to at least 45 degrees, frequent active or passive exercises of the involved leg, antispasmodic drugs and the rapid institution of anticoagulant therapy.

Pulmonary Embolism

As previously indicated, the origin of most pulmonary emboli is from the leg or, rarely, the pelvic veins and is usually the sequel to a case of bland thrombosis because of the looseness of the attachment of the clot consequent to the minimal inflammatory involvement of the vein wall. In thrombophlebitis where inflammation of the vein wall is extensive, embolus production is uncommon (5%). Detachment of a fragment of clot occurs where a large tributary connects with the blocked main vein, the flow of blood from this tributary, being sufficient to break off the "tail" thrombus. Sudden increases in intra-abdominal and consequently intravenous pressure may also produce the same result; this is the reason for the sudden death of patients in the act of using the bedpan or getting up for the first time.

The degree of pulmonary artery blockage depends directly on the size of the embolus, and the size of the embolus depends on the caliber of the vein from which it originates. A piece of clot from the veins of the lower leg will give a minor degree of pulmonary infarction, whereas one from the common femoral or iliac may produce sudden death. Another factor which contributes to the degree of symptoms in pulmonary embolism is spasm of the bronchial tree and pulmonary vessels incident to the sudden lodgment of an embolus, this being similar to the effect of a peripheral arterial embolus. Another similar result is the fact that thrombosis can progress distally from the site of occlusion in pulmonary artery and give a fatal termination to a patient who survived the catastrophe. The rapid drop in h'

associated with pulmonary infarction of major degree is a further cause of death in this condition.

Signs and Symptoms.—Any person suffering from any inflammatory disease, after an operation or childbirth, or who has been confined to bed for any period of time and who complains of a sudden pain in the chest should be suspected of having pulmonary embolism. Minor emboli may be manifested only by a "stitch in the chest" and be so mild that the initial one is not recognized. Pathognomonic is the triad of a sudden pain in the chest aggravated by respiration, breathlessness, and later, hemoptysis. The greater the amount of lung infarcted the more marked are the symptoms. Pallor, cyanosis, collapse, sweating, loss of consciousness, lowered blood pressure, and rapid thready pulse are the signs of a major embolus. Differentiation of this picture from that of an acute coronary occlusion may be difficult, and many patients have died of so-called acute heart attack when the real reason was an embolus. The discovery of the site of the peripheral thrombus, the later spitting of blood, the development of a friction rub, and the x-ray appearance of a dense area in one lung will give the differentiation.

Treatment of Venous Thrombosis and Pulmonary Embolism

Two relatively recent methods have been added in the treatment of this condition with marked improvement in the morbidity and mortality results. These are the employment of the anticoagulant drugs and the judicious use of vein ligation. The aim of present-day treatment is to make a diagnosis at the earliest possible moment and then institute active therapy to prevent extension of the process centrally. It is the emboli from the larger veins which kill or, in thrombophlebitis, it is the involvement of the major veins such as the common femoral or iliacs that produce the crippling sequelae in subsequent years of chronic swelling of the leg, eczema, ulceration (postphlebitic leg).

by careful attention to detail in the patient before and after operation. Anemia, dehydration, and alterations in the albumin-globulin ratio should be corrected prior to operation. Gentleness during the operation

side should be done hourly. Fowler's position should not be used, and tight binders or dressing on the abdomen should be discarded because they limit proper respiratory movements. The patient should be out of bed as

Fig 516—Surgical technique for removal of thrombus in the common femoral vein

reduces the amount of tissue damage and consequently the amount of thrombokinase liberated. Active movements of the legs should be carried out many times daily according to a definite schedule, and turning from side to

early as possible and encouraged to walk and not just sit in a chair. In a case of an elderly patient where extensive surgery has been done or where an increased clotting tendency is suspected by a history of previous episodes

of thrombosis, anticoagulant drugs should be used as a prophylactic measure. The legs should be inspected and palpated daily in every case of major abdominal surgery and treatment instituted at the first suspicion of venous thrombosis. Prophylactic ligation of both superficial femoral veins just distal to the profunda branch has been proposed by some groups prior to major abdominal surgery but the results achieved have not been impressive and do not justify the additional surgery.

The use of suitable vein ligation in the treatment of phlebothrombosis and thrombophlebitis has recently been through a phase of popularity but is now on the wane. The rationale of this procedure was to trap the thrombus distally by a suitably placed proximal vein ligation or, if thrombus was found in the vein when the superficial or common femoral vein was opened, then to suck out the central extension of the thrombus. The ideal site for such a vein exploration and ligation is the superficial femoral just distal to the profunda branch. Ligation at this level does not lead to leg edema or postphlebotic leg changes, and the common femoral up to the common iliac can be cleared by a suction tip.

This reasoning is good in theory but is not so sound in practice. On many occasions the author has found on opening the superficial or common femoral veins that clot is present which cannot be removed because of its internal adherence. In such a case clot reformation is inevitable. Other cases have occurred where a thrombus has formed central to the site of ligation, and resulted in embolism. Again it is frequently impossible to tell from which leg an embolus has originated; consequently a bilateral operation is necessary. Or again it is impossible to say that the thrombus has not originated in the pelvic veins.

At the present time it is the author's opinion that there are only two indications for ligation in venous thrombosis. The first is when the patient continues to throw multiple emboli to the lungs despite treatment by adequate anticoagulant therapy. His life is endangered and further steps must be taken. In this case, femoral ligations are usually inadequate, and ligation of the vena cava below the renal veins is the site of choice.

The second indication is the ligation of the superficial femoral vein just distal to the profunda in the early but severe case of thrombophlebitis when the signs and symptoms are still localized below the knee. The rationale here is not to prevent embolization but to prevent the central extension of the process into the common femoral and iliac veins by dividing the extending pathway. If the process is kept distal to the major veins, convalescence is shortened, but most important, the sequelae of the postphlebotic leg are prevented. It should be emphasized that all patients with deep venous thrombosis treated surgically should have coincident anticoagulant therapy.

Anticoagulant drugs will not dissolve an existing thrombus, but, if correctly used, should prevent its extension. If immediate anticoagulant effect is desired, heparin is used by the intravenous drip method or by intermittent intravenous or intramuscular injection. Dicumarol (200-300 mg.) is started at the same time but, as its effect is not manifest until 36-48 hours, the heparin should be used for this period of time. Newer anticoagulant drugs, Tromexan and Marcumar, have a similar action to Dicumarol, but their effect is more rapidly obtained. The dosage control, by determination of the prothrombin time, is similar to that of Dicumarol. The great majority of cases of venous thrombosis are at present treated by anticoagulant therapy and the below-mentioned adjuvant measures.

When severe pain and edema are present in thrombophlebitis, it is an indication of more than usual arterial and venous spasm. In such cases, blockage of the appropriate lumbar sympathetic chain will relieve this vasospasm and aid recovery. One to four such procaine blocks lessen pain, reduce the edema, and appear to shorten convalescence. Other adjuvant methods in the treatment of acute thrombophlebitis are elevation of the leg as high as is comfortable and active contraction of the muscles of the limb, the first to aid in draining off the edema and the second to aid also in this respect and to prevent muscle atrophy during convalescence.

When a minor embolus occurs, the treatment consists (as outlined above) in energetic attempts to prevent a second. How-

Fig 519 —Postphlebotic ulcer with surrounding eczema and tissue fibrosis

the interval. One of the complications most frequently encountered is that of chronic ulceration. This is seen most commonly just proximal to the medial malleolus. This ulceration should be easily differentiated from the true varicose ulcer by the history of previous deep phlebitis, the absence or paucity of varicose veins, and the other soft tissue changes of deep phlebitis. Other complications are those of eczema involving the lower leg (stasis dermatitis), areas of induration, pigmentation, and subacute inflammation, and the development of secondary varicose veins.

Prevention of the complications of the postphlebitic leg should be the primary aim of treatment. The patient who has recovered from a severe thrombophlebitis should have his condition explained fully. It should be stressed that the leg will never be normal again and that complications can occur if the chronic edema is neglected. A strong elastic stocking should be worn for an indefinite period, employment entailing prolonged standing should be avoided, and the patient should get the habit of elevating the leg whenever possible. Once an ulcer has developed, bed rest with leg elevation and moist hot compresses will result in healing, but recurrence is likely in the future unless the following instructions are carried out.

Instructions for the Continual Care of the Leg Damaged by Phlebitis

- 1 Wear your elastic stocking from the time you get out of bed until you retire, with the exception of bath time. The stocking should be renewed every 3 months, and it is best to have two stockings that can be alternated for cleaning purposes.
- 2 Do not stand for more than 30 minutes without sitting down for 15 minutes and elevating the leg on another chair. When standing, get into the habit of flexing the toes in your shoes and frequently rising on tip toes.
- 3 Plan your day so that you can lie down for 2 to 3 half-hour periods and elevate your leg to a 45 degree angle. The back of a small straight-backed chair is useful for this purpose.
- 4 Whenever you sit down, elevate your leg on a footstool, chair, or chesterfield.
- 5 At night raise the foot of the bed on blocks about 6 inches.
- 6 Apply a bland cold cream to the affected skin at night about every second day.
- 7 Avoid irritation to the involved leg, especially in respect to sunburn and hot-water bottles.
- 8 Be extremely careful to prevent bumping, bruising, or scratching the affected leg.

In the lesser degrees of ulceration, ambulatory treatment with Unna's paste boot or one of its modifications will result in healing, but, again, permanent care of the leg is necessary.

The occasional case of postphlebitic ulceration will be encountered when the ulcer is so large, fibrotic, and long standing that excision and skin grafting are necessary for initial healing. Also some degree of sympathetic dystrophy is seen occasionally in this type of case, and a lumbar sympathectomy will speed ulcer healing and minimize the possibility of recurrence. As mentioned previously, the removal of secondary incompetent varicose veins in the postphlebitic leg will also accomplish the same result. But it cannot be too often emphasized that all treatment is merely partial, the underlying etiologic pathology still remains, and recurrence is almost inevitable unless care is taken to prevent edema and injury to this unhealthy leg.

Phlebitis Migrans

This variety of venous thrombosis is relatively uncommon and consists of multiple waves of thrombophlebitis in short segments of superficial veins of the limbs and occasionally the trunk. This thrombophlebitis occurs in normal veins as distinct from that occurring in varicose veins. The patient complains of hard, reddened tender subcutaneous cords in the location of the superficial veins. One vein segment after another becomes involved, and the condition may last for months. Such a lesion occurs in 30% of cases of thromboangiitis obliterans, and a careful examination of the arterial tree is indicated for many months to rule out this possibility. However, most cases of this condition do not show any immediate or late evidence of thromboangiitis and therefore constitute separate entities. The etiology is not clear, but the author has had many cases where a careful search for focal infections and their removal have resulted in cure. The tonsils are the most important focus and should be removed on the slightest suspicion. Anticoagulants are of little use because of the chronic nature of the disease.

VASCULAR LESIONS DUE TO COLD

(See Chapter 6, Injuries Due to Physical Agents.)

COSTOBRACHIAL COMPRESSION SYNDROME

There is a group of anatomic or developmental anomalies of the shoulder girdle which by compression of the components of the brachial plexus and/or the subclavian artery can cause a variety of signs and symptoms involving the upper extremity. These conditions are cervical rib, scalenus anticus syndrome, costoclavicular syndrome, and abnormalities of the 1st thoracic rib.

affected is the ulnar because its origin from C8 and T1 is most subject to compression due to its anatomic position. The degree of involvement varies from paresthesias to partial motor and sensory loss. The vascular symptoms include attacks of arteriolar spasm resembling Raynaud's phenomenon. These attacks probably are caused by pressure irritation of the sympathetic outflow to the limb, this outflow running with the medial cord of the brachial plexus and with the subclavian artery. Evidence of organic arterial occlusion is sometimes present, which may be severe due to thrombosis of the subclavian artery, the result of prolonged trauma. Or the picture may be that of occlusion of digital arteries to the

Fig 520 --Anatomy of the scalenus area

Signs and Symptoms.—These are common to all the above conditions and can be divided into two main groups, those with evidence of brachial plexus pressure and those with indications of interference with the vascular supply to the limb. A combination of both types may be present. The neurologic picture consists of the symptom of pain localized to the deltoid area or down the arm, most commonly in the distribution of the medial cord of the brachial plexus. The individual nerve most frequently

affected is the ulnar because its origin from C8 and T1 is most subject to compression due to its anatomic position. The degree of involvement varies from paresthesias to partial motor and sensory loss. The vascular symptoms include attacks of arteriolar spasm resembling Raynaud's phenomenon. These attacks probably are caused by pressure irritation of the sympathetic outflow to the limb, this outflow running with the medial cord of the brachial plexus and with the subclavian artery. Evidence of organic arterial occlusion is sometimes present, which may be severe due to thrombosis of the subclavian artery, the result of prolonged trauma. Or the picture may be that of occlusion of digital arteries to the

fingers, presumably on the basis of prolonged spasm. Cold bluish-red fingers result with pain and trophic changes which may be severe enough to produce digital gangrene. When arterial occlusion is present in the subclavian artery, the distal pulses will be palpable or weak, depending on the efficiency of the collateral circulation. The blood pressure in this arm will be low or unobtainable.

The patient will volunteer the information in many cases that carrying heavy objects in

this hand will aggravate symptoms, also that he cannot sleep on this side at night because the hand and arm "go to sleep" and develop pins-and-needles sensations. He finds greater comfort by sleeping with his arms above his head. A definite test (Adson's maneuver) has been devised which indicates that subclavian artery compression is taking place. This is designed to indicate scalenus compression but applies equally well to the other varieties of shoulder girdle compression. A perusal of Fig. 521 will indicate the performance of these tests.

In the differential diagnosis of these compression syndromes, especially where pain and neurologic signs are present, certain other conditions should be considered and ruled out before a positive diagnosis of shoulder girdle

rib is of all varieties, from small stubs to a complete rib articulating with the 1st thoracic rib. Also seen is a short bony rib with a cartilaginous or fibrous cord articulating with the first rib in the region of the scalene tubercle. These accessory ribs are usually bilateral but frequently only one side gives symptoms. The medial cord of the brachial plexus, the sympathetic supply to the arm, and the subclavian artery have to pass over this rib before descending into the arm and consequently are subjected to pressure. Prolonged pressure on the subclavian artery by the cervical rib may cause the condition known as post-stenotic dilatation of the artery where an aneurysmal like dilatation of the vessel occurs distal to the point of compression. This unusual effect has been shown to be the result of

Fig 521—Steps in the performance of the Adson maneuver

compression can be made. Prolapse of a cervical intervertebral disc is a common cause of this so-called brachial neuritis as is also nerve pressure following osteoarthritis, involving the intervertebral foramina. The medical conditions of neuritis subsequent to diabetes, alcohol, lead poisoning, and vitamin B deficiency should also be kept in mind.

Cervical Rib

About 0.5% of all persons have a cervical rib arising from the 7th cervical vertebra. This

marked disturbance in the hemodynamics at this area. The turbulent and slowed blood flow in this dilated portion predisposes to the occasional complication of thrombosis and the resultant ischemic changes in arm and hand. However, many persons have cervical ribs without symptoms, and, in many others, symptoms do not develop until middle life. The late development of symptoms in cervical rib is probably due to the fact that, as age advances, the posture becomes more stooped and the muscle tone of the shoulder girdle relaxes,

allowing the shoulder to fall forward and downward, thus giving a greater likelihood of compression.

At the Royal Victoria Hospital a series of 40 cases of cervical rib has been studied, of

pain and motor or sensory changes. Three showed pure vascular signs only, whereas 5 others had a mixed vascular and neurologic symptomatology. Fifteen of the 20 patients with symptoms required operation.

Fig 522—Case of subclavian artery compression due to cartilaginous extension of cervical rib

Fig 523—Bilateral cervical ribs, only that on the right gave symptoms

these 29 were in females and 11 in males, 25 were bilateral and 15 unilateral, and only half of this number had symptoms. Neurologic manifestations preponderated, with 17 showing

The diagnosis of cervical rib is confirmed by x-ray, and surgical treatment consists of section of the scalenus anticus muscle. Resection of a part or the whole rib is, in most

cases, unnecessary. Surgical therapy is, however, reserved for the more severe cases, whereas physiotherapy designed to improve posture and muscle tone in the shoulder area is frequently sufficient in the milder manifestations.

Fig 524—X ray of congenital abnormality of upper dorsal spine with elevation of the right 1st rib which acts similarly to a cervical rib

Scalenus Anticus Syndrome

A study of the anatomic drawing will show the anatomic arrangement of this muscle as it attaches to the 1st rib anterior to the brachial plexus and subclavian artery. Spasm or hypertrophy of this muscle narrows the tunnel through which the neurovascular bundle emerges into the arm. This occurs in two ways: the scalenus anticus can cause pressure between itself and the scalenus medius, especially if the latter is abnormally large and more medially placed and, second, subsequent to the muscle spasm the 1st thoracic rib is elevated, causing further compression of the outlet to the arm.

Scalenus anticus syndrome is suspected by the previously mentioned signs and symptoms, local tenderness to pressure over the insertion of the muscle, positive scalene tests, and the absence of the other conditions mentioned in the differential diagnosis. An important confirmatory test in both cervical rib and scalenus syndrome is the finding of a systolic bruit over the subclavian artery in the neck which is accentuated during the performance of the Adson test.

The treatment is on the same lines as that for cervical rib, with the exception that the surgical therapy required is only section of the scalenus anticus muscle (scaleneotomy) as close to its insertion into the 1st rib as possible.

A

B.

Fig 525—A, Normal venogram of the upper extremity
B, Axillary vein compression with stasis due to costoclavicular compression

Disorders Caused by Abnormalities of the First Thoracic Rib

These are uncommon and only occasionally result in symptoms. The abnormality which is concerned here is a broadening and thickening of the lateral portion of the rib over which the neurovascular structures pass. One feature seen in this variety and that of costoclavicular compression is varying degrees of obstruction to the venous return of the arm. Anatomically, the subclavian vein cannot be compressed by a cervical rib or the scalene muscles, but in abnormalities of the 1st rib or in costoclavicular compression, the vein is affected with the neurovascular bundle.

Surgical treatment may require removal of this section of rib or, more frequently, scalenotomy is all that is necessary. Total removal of the clavicle is also effective.

Costoclavicular Compression

Pressure of the clavicle when pulled downward and backward can cause neurovascular compression against the 1st rib. This factor is rare and is to be suspected only when typical compression symptoms are present and all other causes have been excluded. Treatment is similar to that of scalenus anticus syndrome. Recently, total resection of the clavicle has been advocated so as to remove the upper compressing bone.

Lymphatic System

Josephus C. Luke, MD

EMBRYOLOGY

The lymphatic system has been described as being the "third system" in the body's fluid transportation mechanism and is concerned with the return of tissue fluids through various filtration stations back to the general blood stream. The origin of the lymphatics is still not specifically known, but it is generally agreed that the lymphatics primarily develop from the venous system. The histology is very similar, the vessels are valved, and, anatomically, the two systems are in close approximation.

According to Sabin, the lymphatic system commences from a series of sacs situated close to the confluence of the principal large veins. From these sacs the lymphatic vessels sprout distally and so form the peripheral lymphatic system. The primary lymph sacs are initially formed from a confluence of venous capillaries and are situated on either side of the base of the neck as the jugular sacs, in the retroperitoneal area as the celiac sac, and in each inguinal region as the inguinal sacs. All these become connected, and from them develop not only the lymphatic channels but also the principal masses of lymph nodes. The thoracic duct originates from intercommunication between the celiac and left jugular sacs and receives the communications from both iliac (inguinal) areas. The right lymphatic duct develops from the right jugular sac.

An alternate theory is that the lymphatic vessels have a distal origin from the venous

system and progress centrally until they fuse into the above-mentioned sacs and intercommunicators. A practical application of lymphatic embryology is the fact that the condition known as cystic hygroma, found almost invariably in the neck, is probably the result of a remnant and maldevelopment of one of the jugular sacs.

ANATOMY

Most tissues of the body contain lymphatic capillaries, the exception being those organs or structures which do not contain a normal vascular system. For example, endothelial linings such as the peritoneum or pleura, cartilage, the cornea, and the membranous labyrinth do not contain lymphatic vessels. The central nervous system is devoid of lymphatic vessels because the lymph formed drains directly into the cerebrospinal fluid and, in fact, composes this fluid. Lymphatic capillaries are numerous in proportion to the blood supply to the part, being, therefore, more frequent in such structures as the skin than in the subcutaneous fat. These capillaries are in general larger than the corresponding vascular ones, are lined by endothelium, have a somewhat beaded appearance, and possess bicuspid valves in the larger radicles.

In the skin the lymphatic capillaries are so numerous that no trauma to the skin or injection into the skin can take place without opening numerous lymphatic channels, and so it should be assumed that any injection, be it

intra-dermal, subcutaneous, or intramuscular, is absorbed via the lymphatic system. In the leg a somewhat unique construction of lymphatic vessels occurs with two separate systems (the superficial and deep) only connecting at two locations, the popliteal region and fossa ovalis. No intercommunication occurs through the deep fascia except at these points. This fact is important in an understanding of the relatively frequent condition of lymphedema of the lower extremity.

Situated along the return lymph drainage are strategically placed collections of lymph nodes whose function it is to filter the incoming lymph and so remove foreign material, including bacteria. The nodes contain large numbers of phagocytes that play an important part in the destruction of entering bacteria and

cemia. It is believed that infection reaches the blood stream almost entirely by the lymphatics, this including the viruses whose passage through the lymph nodes is relatively unobstructed.

It can be seen that a detailed knowledge of the various channels of lymph drainage from an organ or region of the body is of prime surgical importance not only from the point of view of the spread of infection but also for a knowledge of the spread of tumor growth. In the majority of malignant tumors, extension is primarily by the lymphatics, and consequently the route of extension can be relatively accurately predicted. Removal of the involved lymphatics and the related nodes is therefore of paramount importance in seeking the cure of a carcinoma.

Lymph Nodes and Vessels

As indicated above, the lymph channels of the lower extremity consist of the superficial and deep sections which communicate only at the popliteal region and through the fossa ovalis in the upper thigh. The superficial channels of the lateral aspect of the foot and leg follow the course of the small saphenous vein, emptying into the deep system at the popliteal space. Before entry into the deep channels, the lymph is filtered by 2-3 popliteal lymph nodes. The medial aspect of the foot and leg and most of the thigh drains into channels which follow the course of the great saphenous vein and join the deep system through the fossa ovalis. Here they pass through the femoral (subinguinal) group of lymph nodes. The corresponding side of the scrotum or labia also drains through the femoral nodes. This group is commonly affected by chronic and acute inflammations in the foot and leg.

Drainage from the buttocks, external genitalia, anal region, vagina, and cervix passes to the inguinal nodes which are situated parallel and superficial to the inguinal ligament. These nodes are frequently involved in venereal infections, skin infections in the drainage area, and cancer of the genitalia, including the cervix. Both the femoral and inguinal nodes drain to the iliac nodes and thence to the main lymphatics of the pelvis, retroperitoneal area, and receptaculum chyli.

Fig. 126.—Filtration mechanism of a lymph node

also are undoubtedly concerned in antibody production. Enlargement of the lymph node occurs during the filtering process (catarrhal lymphadenitis). Occasionally the bacterial invasion is sufficiently large or virile that the lymphadenitis goes on to necrosis and abscess formation. Or, again, if the infection reaching the nodes is not too virulent and is continuous though mild in type, a state of chronic hyperplasia and fibrous tissue reaction occurs in the nodes and results in permanent palpable nodes (chronic lymphadenitis). These filters can be sufficiently overwhelmed by a virulent infection so that not only does suppuration of the node occur but also the infection continues on past one or more nodes to reach the blood stream and so produce a bacteremia or septi-

LYMPHATIC SYSTEM

In the abdomen, the nodes are very numerous both in the mesenteric area and retroperitoneal spaces. The lymphatic vessels and collecting nodes follow the blood supply closely and are located in the mesenteric attachments of the organs. In the stomach the

Fig 527—Lymphatic drainage of colon

Fig 528—Lymphatic drainage of the stomach

nodes are clustered on either curvature of the stomach, about the lower esophagus, and in the region of the first part of the duodenum. Those draining the small intestine are located in the mesenteric leaves, and frequently the lymphatic vessels leading to these nodes show as small white threads in the bowel wall due

to the milky appearance of the lymph because of the high fat content. This milky lymph (chyle) is also seen in the receptaculum chyli and the thoracic duct, because of the large amount of the lymph collected from the intestinal tract. The degree of milkiness will, of course, vary with the food intake.

The hilar region of the lungs and the mediastinum are especially well supplied with lymph nodes which are a mottled grayish-black color due to the phagocytosed carbon particles which have reached them from the lungs. Also, these nodes are frequently the final resting place of lesser degrees of tubercle infection which has entered through the lungs and which has been overpowered at this first

Fig 529—Lymphatic drainage of head and neck

line of defense. As in the abdomen, these arrested tuberculous nodes frequently reveal themselves as serrated calcified spots. Efferent drainage from the mediastinal nodes is mainly to the thoracic duct, but some from the right lung empties into the right lymphatic duct.

The lymphatic drainage of the breasts is of great surgical importance because of the frequency of breast cancer (see Plate 9).

The head and neck have a superficial and deep set of vessels and nodes. The scalp drainage, as in the remainder of the head and neck, is similar on both sides, and the vessels drain sectionally to specific sets of lymph nodes. The occipital, posterior auricular, and parotid nodes receive the scalp lymph, and their

efferents connect with the superior deep cervical nodes. The lymphatic return from the parotid gland, nasopharynx, mouth, lips, and tongue travels through the submaxillary lymph nodes, and that of the tip of the tongue and central part of the lower lip and mouth travels through the submental nodes. Further drainage thence is to the superior deep cervical or directly to the inferior deep cervicals and then to the blood stream via the right lymphatic duct on the right or directly into the internal jugular-subclavian vein junction on the left in association with the thoracic duct.

The upper extremity has few lymph nodes in comparison to its bulk. One node is placed just proximal to the medial epicondyle and receives the drainage from the ulnar aspect of the forearm and hand including roughly the 4th and 5th fingers. The remainder of the superficial and deep lymphatic drainage progresses directly to the axillary group of nodes which lie in the subcutaneous tissues of the axillary space and are readily palpable when enlarged.

PHYSIOLOGY

Lymph is a collection of tissue fluid and, as such, closely resembles blood plasma. The red cell count is understandably low, varying from 500-10,000/c mm. The white cell (mainly lymphocyte) count is usually double this amount. This is so because of the discharge of lymphocytes into the lymph during its passage through the lymph nodes. The protein content is lower than that of blood but varies markedly, depending on the lymphatic area studied and especially (where thoracic duct lymph is being studied) on the time, whether before or after a meal. As a rule, the protein content is about half that of the plasma. The fibrinogen and prothrombin content is low and, consequently, lymph clots but more slowly than blood. Most of the other constituents—such as nonprotein nitrogen, chlorides, sugar, urea, uric acid, and calcium—have much the same content as the blood.

The lymph pressure and rate of flow are subject to many variables. Studies on thoracic duct fistulas indicate that 1-2 ml. of lymph are lost per minute. Peripheral lymph has a greater pressure than that in the main chan-

nels, the pressure decreasing following passage through a lymph node. The pressure in a normal peripheral vessel rarely exceeds 50 mm of water.

Certain abnormal conditions increase the flow and pressure of lymph. Heat increases production and flow of lymph and, along with the resultant hyperemia, is the reason for the beneficial effect in the treatment of infections. Heat is probably also an accessory factor (in association with prolonged standing) in producing ankle edema in many persons during the heat of summer. Muscle activity increases lymph flow. Also, any factor producing edema obviously increases production and return flow. Examples of this latter group are increased venous pressures and anything that damages the capillary endothelium, allowing increased capillary permeability. This applies particularly to inflammatory edema.

A decrease in the flow and pressure of lymph results from cold and particularly immobility. Congenital malformation of the peripheral lymphatic collecting system, such as those probably present in Milroy's disease and lymphedema praecox, produce decreased flow and varying degrees of lymph stasis with consequent dilatation of the peripheral lymphatic channels. Surgical removal of main lymphatic trunks, their blockage by cancer cells, or infection also gives rise to clinical evidence of lymphatic obstruction with edema.

ACUTE LYMPHANGITIS

In acute inflammations the lymphatic vessels are rapidly affected because of the marked number of cutaneous and deep lymphatics, and extension, local or distant, takes place mainly via the lymphatic system. This spread can be of the local diffuse type when the massive cutaneous lymphatic network becomes involved with coagulated infected lymph and cellular debris. The picture is that of a red, warm, tender, edematous area surrounding the local portal of entry, and the picture is known clinically as cellulitis. Some degree of cellulitis is always present following a surface infection, but the degree varies. Erysipelas is a type of cellulitis but rapidly extending and massive and the result of streptococci. Local edema is the result of the increased tissue fluid produced

is indistinguishable from that of acute appendicitis and consequently the diagnosis is usually made at operation done for a supposedly acute appendix. Red, swollen, and markedly enlarged nodes up to the size of a walnut are found with little evidence of any inflammation of the terminal ileum or appendix. Rarely does suppuration with abscess formation occur, and the usual outcome is rapid subsidence of the condition following appendectomy and the use of the antibiotic drugs.

Chronic Mesenteric Lymphadenitis.—In common with all lymphatic tissue, the lymph nodes in childhood and adolescence are more hyperplastic than in later adult life. The mesenteric nodes share in this involvement and, as a result, produce symptoms due to their rigidity where mesenteric movement is involved. The patient is usually a child 3-13 years of age who complains of intermittent spasms of abdominal pain. The spasms may be momentary or persist up to 15-30 minutes. The pain is not typical colic but is described as an intermittent knifelike pain centered about the umbilical region. Nausea, vomiting, and anorexia are occasionally associated. Vague tenderness is present in the right lower quadrant or mid-abdomen, but splinting is minimal or absent. A mild degree of fever occurs in most cases, but the leukocyte count is little if any elevated. The local point of tenderness is found either in the right lower quadrant or subumbilical region frequently shifts to the left when the patient is turned on the left side (Brennan's sign). The significance of this is the positional shift of the mesentery with its offending enlarged nodes. Such a shift does not take place when the cecum and appendix are involved.

The diagnosis is difficult to distinguish from chronic appendicitis, but the above-mentioned points should tend to indicate the possibility of chronic mesenteric adenitis. Active therapy is necessary only if symptoms persist and interfere with the activities and nutrition of the child. Normally the complaints will disappear with time, especially after puberty. However, when of a disabling nature or when chronic or subacute appendicitis cannot be excluded, then appendectomy is indicated.

On opening the abdomen a somewhat increased quantity of straw-colored peritoneal fluid is encountered. The lymph nodes in the small bowel mesentery are numerous and enlarged up to the size of a bean. Biopsy of one of these nodes invariably shows a catarrhal lymphadenitis. Removal of the relatively normal-looking appendix is all that is indicated in these cases and appears to bring about a complete regression of signs and symptoms in most cases. Formerly it was considered that these enlarged lymph nodes were a chronic hyperplastic form of tuberculous adenitis, but pathologic examination of many nodes removed for biopsy failed to confirm this idea, also bacteriologic study of the removed node always fails to yield any growth.

Specific Forms of Lymphadenitis

Tuberculous Lymphadenitis.—This form of lymph node involvement is much less frequent than formerly in North America because of the strict control of the public sale of milk. Pasteurization has reduced this disease to a minimum, especially among city dwellers, and the cases now seen usually come from the country in areas where pasteurization is not used. In England, Scotland, and Wales less stringent milk control still produces a large number of node, bone, and joint tuberculosis.

Tuberculous adenitis in the child is almost invariably the result of the bovine type of bacillus acquired from infected milk, but in the occasional adult case the organism can be either bovine or human in type. The lymph nodes of the neck are most frequently involved, the germs entering the lymphatic system from a tonsillar focus or through one of the pharyngeal lymph plaques, infected tooth, or other break in the lining of the oral cavity. The organism can come via infected milk or sputum coughed up from a pulmonary lesion.

The mesenteric lymph nodes are next most commonly involved, becoming infected from organisms absorbed from the gastrointestinal tract originating either in infected food and drinks or the swallowing of tuberculous sputum. The ileocecal region is the most frequent portion of the gastrointestinal tract to be involved. An x-ray of the abdomen taken for other reasons frequently shows an irregular

roundish patch of calcification about 1.25 cm. in diameter. These are tuberculous nodes in which the process has finally been conquered but not before node destruction and later calcification of the caseated node have occurred. This finding can be associated with no past or present signs or symptoms of the disease, and such a finding is common also in routine chest radiography.

Nodes draining one of the extremities are rarely involved by tuberculosis unless the organism gains entrance to the distal tissues through a small abrasion. Such an accident is most common in persons such as nurses whose work brings them in contact with open cases of tuberculosis. A localized, firm, tender, painful nodule develops in the skin at the site of accidental entry of the germ. A small, shallow, painful ulcer usually develops at this site, and, later, enlarged, tender regional nodes appear. The local finger lesion was formerly known as a butcher's wart because of the frequency of this condition in those who handled infected meat.

Pathology.—When the bacillus of tuberculosis is conveyed to a lymph node by the lymphatics, the reaction in the node depends on the degree of invasion and the resistance of the host to the invader. All degrees of node response may occur from single node hyperplasia to that of caseation and abscess formation. In the lesser degrees, typical tubercle formation may be hard to find, making the determination of the correct diagnosis difficult even on pathologic section, therefore the diagnosis may be easily mistaken for chronic non-specific lymphadenitis.

Clinically, the nodes are initially discrete and elastic but later become matted into masses due to the development of periadenitis. An actively infected or caseating node may rupture into the blood stream and result in the military generalized form of the disease. In the more advanced cases tubercles are numerous, areas of caseation are obvious, and the typical "cold abscess" of tuberculosis may result. Incision and drainage of such an abscess under the mistaken impression that it is due to pyogenic organisms invariably produce a fistula which remains as a discharging sinus indefinitely because of the underlying infected

nodule and the inevitable secondary infection incident to the draining wound.

The moral to be emphasized in this connection is to suspect all abscesses which have developed in a subacute manner, especially in the neck. In the tuberculous case, the constitutional reaction is minimal, the origin of the infection is obscure, and the abscess shows minimal signs of inflammation, tenderness, and surrounding induration. When doubt exists, the pus should be aspirated and cultured, and if tubercle bacilli are found, then incision of the infected abscess is indicated with removal by curettage of the underlying infected node or nodes.

Formerly, extensive surgery including block dissection of all the neck nodes was the accepted procedure in tuberculous adenitis, but at present such an extensive degree of the disease requiring such treatment is rarely seen. Improvement in the medical management has also decreased the need for surgery. Control of the milk supply, removal of infected tonsils, improvement in general health subsequent to adequate rest, nourishment, vitamins, and heliotherapy will result in cure in most instances. As indicated above, the role of surgery in tuberculous adenitis is the evacuation of abscesses and the local removal of caseating abscessed nodes. Streptomycin combined with either para-aminosalicylic acid or one of the isoniazid group of drugs is the most recent successful aid to treatment.

Syphilitic Lymphadenitis.—Involvement of lymph nodes is seen in both the primary and secondary stages of syphilis. In the former, the nodes adjacent to the chancre become involved in 5-14 days following inoculation. The inguinal nodes are therefore most commonly involved, and the nodes present as firm, discrete, tender nodules. The adenitis is due to a combination of the *Spirochaeta pallida* and other secondary invaders from the chancre. The diagnosis is not difficult when the chancre is seen and is confirmed by dark-field examination of the secretion. The secondary stage of syphilis is frequently associated with a generalized lymphadenopathy, the nodes again being discrete, rubbery, and nontender and do not go on to suppuration. Tertiary gumma in lymph nodes is extremely rare and will be less common in the future because of the decrease in incidence,

improved detection, and improved treatment of this disease

Lymphogranuloma Venereum (Lymphogranuloma Inguinale).—This condition has been called the fourth venereal disease and is caused by a filtrable virus. The genitalia are the most common site of entry, but of course digital and oral origins can occur. The initial surface lesion rarely is as large as a chancre and may be so insignificant as to go unnoticed. Several weeks after contamination, the regional nodes become swollen, indurated, and painful. Necrosis of the node results and suppuration occurs. This pus tends to burrow to the surface or surrounding structures unless aspiration is carried out. In the inguinal region, ulceration and sinus formation with later extensive scarring are the usual sequelae. In some cases extension to the perirectal tissues with perineal or rectal fistula takes place. The incidental scarring subsequent to this type of spread may result in extensive stricture formation of the lower rectum. Such a sequel appears to be more common in females, and these strictures were formerly supposed to be syphilitic in origin because the pathologic picture is that of a nonspecific granuloma.

The diagnosis should be suspected from the clinical picture of the inguinal bubos or the presence of a rectal stricture. Carcinoma and posthemorrhoidectomy strictures should be excluded. The Frei test gives confirmation to the diagnosis and consists of an intradermal injection of diluted pus taken from one of the lesions and autoclaved at 56° C. A positive test is indicated by a central papule at the site of injection with more than a 1 cm ring of surrounding erythema. Treatment consists of aspiration of abscesses and the use of massive doses of Aureomycin and penicillin.

Hodgkin's Disease

Definition.—In 1832 Hodgkin described a series of glandular swellings associated with splenomegaly and made the first description of the disease which bears his name. It is likely that he described other lesions in his original paper, but four of the cases appear to fit closely with what we now know as Hodgkin's disease. The etiology of this condition has not been clearly settled because it shows not only

many of the features of an infective granulomatous lesion but also those of a malignant tumor, being particularly invasive in its final stages.

Jackson and Parker have made a differentiation of varying stages of this disease and have called the initial stage *Hodgkin's granuloma*, indicating that the pathologic picture is close to but not typical of Hodgkin's. This is an important differentiation because of the pathologic difficulties in labelling one of true Hodgkin's disease. The author has several cases in which a pathologic probable diagnosis of Hodgkin's disease has been made and a poor prognosis given, only to have the patient continue in good health or with further episodes of symptomless glandular enlargements for more than 15 years. It is obvious that such longevity indicates features not in keeping with true Hodgkin's disease in which the prognosis is fatal in 1-4 years. This latter fatal group is called, by Jackson and Parker, *Hodgkin's granuloma*. The malignant, invasive variety of Hodgkin's disease which appears to progress from the granulomatous stage has been called, by Ewing, *Hodgkin's sarcoma* and appears mainly in the older age group. Therefore it would appear wise to divide this disease into the three above stages, each of which has to be settled by a combination of clinical and pathologic criteria.

Diagnosis.—The sex incidence appears higher in males (3:1), and the disease may occur at any age. The paraganuloma is seen mainly in postpubertal adults, the granuloma in the early adult age, and the sarcomatous type in the older age groups. The patient usually presents himself with a gradually progressive enlargement of various lymph nodes particularly those of the neck. In the early stages (paraganuloma and early granuloma stage) the constitutional symptoms are absent but later weight loss, anorexia, anemia, and pressure symptoms from the node masses are present. An unusual variety of unexplained fever (Pel-Ebstein) is occasionally associated with this disease. The temperature rises over a few days to a level of 101°-103° and is maintained at this level with minor variations for 7-14 days, after which it returns to normal. Recurrent bouts of this pyrexia usually occur.

Plate 64.—Hodgkin's Disease.

The spleen is moderately enlarged in about 70% of the cases, and blood examination shows, in the later stages, a definite anemia, occasionally eosinophilia, and an increase in large mononuclear leukocytes. These blood changes are seldom sufficiently characteristic to be diagnostic. Primary involvement of the gastrointestinal tract can occur.

Pathologic Appearance.—The lymph nodes are enlarged but remain discrete and rubbery until the late stages. They have an elastic consistency unlike the rocky hardness of secondary cancer deposits in nodes. On section the node shows a gray, translucent appearance, markedly different from the encephaloid appearance of secondary cancer. In microscopic section, the characteristic points are the replacement of the normal lymphoid tissue by a multitude of different cell types. The most prominent of these is a large, pale epitheloid cell, but most characteristic are the giant cells. The latter are mononucleated or multinucleated and are called after their discoverers, Reed and Sternberg. This characteristic cell is found both in the paraganuloma and in the granuloma. Other cells present include eosinophils, lymphocytes, and monomorphonuclear and polymorphonuclear leukocytes. The above picture is also seen scattered in other organs, especially the spleen, liver, and bone marrow. Hodgkin's sarcoma usually shows direct extension of the disease into lung, bone, liver, and portions of the gastrointestinal tract.

Treatment.—Treatment is a combination of surgery and radiotherapy. Surgery is indicated mainly for the purpose of obtaining biopsy material, but it is wise to remove the entire enlarged node at time of operation rather than a mere portion of the node. X-ray therapy produces remarkable regression of the enlarged nodes and is used in different locations as new node masses arise. In the paraganuloma, the regression following x-ray therapy may last for years, but once the disease is well established, the benefit from this therapy is only temporary as other manifestations soon arise. However, there is no doubt that x-ray therapy is the best therapeutic agent available, but unfortunately recurrent enlargement of the original nodes following x-ray

responds less favorably on secondary irradiation. Teroplerin and nitrogen mustard may be useful in the terminal stage to give some alleviation of symptoms but are purely palliative.

Lymphosarcoma (Lymphoblastoma)

Definition.—This very fatal disease can be considered a primary neoplasm of lymphatic tissue. It has the characteristic of appearing in scattered areas of lymphatic tissue almost simultaneously. There is considerable clinical resemblance between this form of lymphatic abnormality and that of Hodgkin's disease as the initial complaint is that of a lump in one of the lymph node areas. As in Hodgkin's disease the neck is the commonest site of origin, although the groin and axilla are also frequently primarily involved. The individual lymph nodes rapidly become fused from local extension of the tumor and even may ulcerate through the skin.

Diagnosis.—There are no specific symptoms of the disease, the patient seeking attention because of a lump or symptoms which are the result of pressure and involvement of surrounding structures. The spleen may be found to be somewhat enlarged. Similar to Hodgkin's disease, the blood changes are not characteristic but usually show a leukocytosis which can be caused by either an increased lymphocyte or polymorphonuclear count. In the former type, confusion may result from the resemblance to lymphatic leukemia. Anemia and some fever are frequently associated with the late cases and generalized metastases may be spread throughout solid organs. Lymphatic leukemia may develop in a case of lymphosarcoma and vice versa, especially in childhood when the greatest incidence of the disease takes place.

Not only lymph nodes but other lymphoid structures are primarily the seat of the disease. These include the tonsils, the adenoids, and the gastrointestinal lymphoid tissue. In the gastrointestinal tract the stomach is the organ most commonly affected, and the preoperative clinical x-ray picture is indistinguishable from carcinoma. The ileum with Peyer's patches may also show the first signs of the disease, whereas the rectum and the colon are next in fre-

quency. At the Royal Victoria Hospital 23 cases of primary lymphosarcoma of the gastrointestinal tract were found in a total of 100 cases of this disease.

Cases of Lymphosarcoma.—

Generalized spread	56
Primarily retroperitoneal	21
Gastrointestinal	23
Stomach	6
Duodenum	3
Jejunum	2
Ileum	3
Cecum	3
Colon—other parts	3
Rectum	3
Total number of cases	100

Pathologic Features.—The gross appearance of the cut node is not characteristic. It is whitish gray to pink in color and is softer than the corresponding node of Hodgkin's disease. Fusion of contiguous nodes occurs early in the disease.

Microscopically, two main varieties of pathologic types are distinguished. The more common is that in which the node appears to have been replaced in its architecture by a diffuse collection of small round cells resembling small lymphocytes. Occasionally a larger type of lymphocyte is seen similar to the appearance of a lymphoblast. This variety shows a uniform pathologic appearance differing markedly from the pleomorphic cell types of Hodgkin's disease. Giant cells do not occur in lymphosarcoma. In the second variety, the reticuloendothelial elements appear to be primarily involved, and consequently it has received the name of a *reticulum cell sarcoma*. It is argued by some authorities that this is not a variety of lymphosarcoma but a separate tumor which arises from the reticuloendothelial system of lymph nodes. Especially does this concept hold when it is known that this type of tumor can be primary in bone and other tissue where lymphatic tissue is minimal. In the lymph node, the structure is destroyed and is replaced by large, pale staining cells of endothelial type, arranged loosely and with a more pronounced reticulum than in the lymphoid type.

It must be borne in mind that diagnosis of one of the lymphomas on pathologic appearance only may contain a margin of error be-

cause of the considerable variations in the picture from case to case. At times, a simple hyperplastic lymph node may be difficult to differentiate from the lymphatic variety of lymphosarcoma, consequently diagnosis should be made in combination with a suggestive clinical picture and a progressive clinical course. It is likely that patients with lymphosarcoma who survive many years have not had authentic cases of the disease.

Treatment.—Treatment is similar to Hodgkin's disease, with surgery being limited to the obtaining of material for biopsy. Radiation therapy produces a rapid melting away of the nodes and relief of symptoms, but, unfortunately, the disease usually recurs in other areas. Radiation therapy can be used as a diagnostic test, especially in those cases in which the mediastinal nodes are involved. The obtaining of biopsy material is not practical in such cases, and if the symptoms rapidly decrease and the chest picture rapidly improves under treatment, it is likely that lymphosarcoma is the cause of the glandular enlargement. As in Hodgkin's disease, nitrogen mustard is of some palliative benefit in the advanced cases. Cortisone and ACTH therapy has so far been disappointing in the treatment of lymphoma.

Brill's Giant Follicular Hyperplasia (Giant Follicle Lymphoma)

This variety of lymph node enlargement is of importance because of its potentialities. Pathologically it is characterized by the large number of hypertrophied lymphoid follicles seen in the node. These can often be seen grossly in the freshly cut node. The enlarged follicles are packed with actively proliferating lymphocytes sufficiently neoplastic as to invade the node capsule. As a rule only a few nodes are involved, and it is rarely that the disease becomes generalized.

The importance of this variety of lymphoma is the frequency of its progression (about 65%) to one of the more malignant lymphomas. Lymphosarcoma, either lymphocytic or reticulum cell type, is the most frequent, but Hodgkin's disease has also been reported to arise from this focus. Radiation therapy is the best treatment, but constant observation must be made for possible future developments.

THE THYMUS

Although generally considered a portion of the lymphatic system, the thymus is composed of two separate elements. The medulla is derived from the 4th branchial cleft and is composed of epithelial cells derived from the cleft. These are mainly collected in cell aggregations known as Hassall's corpuscles whose function is not fully known. The thymic cortex is composed mainly of lymphocytes, and the variations in size of the organ during disease states and in varying ages are mainly due to the increase or decrease of the lymphocyte content.

In disease states, the thymus decreases in size due to loss of lymphocytes, whereas in sudden death the gland size corresponds to the normal. This latter finding was formerly mistaken to indicate a pathologic increase in the size of the gland, especially in infants and children, with sudden unexplained death. The terms *status thymolymphaticus* and *thymic death* were coined in an attempt to describe these cases, but it has been shown that these so-called enlarged thymus glands were either normal or little enlarged. At birth the gland weighs about 13 Gm., and increases to 35 Gm. at puberty, gradually becoming atrophied in adult life. The thymus rarely is sufficiently enlarged to produce direct pressure symptoms on the trachea but should be kept in mind in cases of unexplained moderate dyspnea. X-ray, including anteroposterior and lateral projection, will give the clue to such a condition. In diseases which result in lymphatic hypertrophy, the thymus is also enlarged, including lymphatic leukemia and Graves' disease.

Tumors

As the thymus consists of the two separate elements, cortex and medulla, it is heir to rare tumors involving the cortical lymphatic tissue or the epithelial-celled medulla. The former type resembles lymphosarcoma either of the lymphocytic or reticulum-celled type and is known as *malignant thymoma*. The epithelial cell type is a true *carcinoma* arising from Hassall's corpuscles. Both varieties are highly malignant and rapidly fatal, yielding only briefly to x-ray therapy. Local compression and

invasion of the chest structures and lymphatic node spread occur early. General metastases sometimes are found.

PERIPHERAL ABNORMALITIES OF THE LYMPHATIC SYSTEM

Tumors of Lymphatic Origin

Tumors of the lymphatic system are relatively rare if the dilated lymph spaces associated with acquired or congenital lymphedema are excepted. True lymphatic tumors can be divided into the simple, the cavernous, and the cystic. The *simple lymphangiomas* are usually congenital and are manifest as small warty tumors on the skin or mucous membranes. They are elastic to the feel and white to pink in color and consist of a meshwork of dilated lymph spaces and lymph vessels set in a thin reticular network. The *cavernous type* is also congenital in origin and is frequently combined with hemangiomatous tissue. Large areas of the skin and subcutaneous tissue may be involved and result in a tumor-like mass of dilated vesicles containing lymph with a spongy mass of grayish tissue in which are mingled spots of hemangiomatous tissue. These tumors are most commonly seen in the upper extremity and shoulder region, the lips, eyelids, and tongue. Surgical excision is the best therapy, but recurrence will take place if not totally removed. X-ray and radium can be used but are probably most effective where excision has not been total or where recurrence has taken place.

Cystic lymphangioma (cystic hygroma) is also congenital and develops from endothelial cell rests remaining from the formation of the embryonic jugular sacs from which the lymphatics of the head, neck, and arms develop. They are most common at the base of the neck but may occur in the situations of the other primary embryonic lymph sacs (inguinal and celiac). Cystic hygromas may be well developed at birth and cause dystocia or may develop in early childhood. The typical one is a large, soft, cystic swelling in the supraclavicular area, lobulated, and containing large quantities of lymph. Well-marked transillumination occurs. In common with other lymphatic collections, they become infected easily, and

treatment should be carried out early to prevent this complication. Radical surgical excision is the best therapy.

LYMPHEDEMA

The development of the lymph vessels is closely akin to that of the veins and they resemble veins in being endothelial-lined tubes containing valves. They closely follow the main vascular channels. The lymph in these channels is strained through various sets of lymph nodes and is collected in the main lymph ducts which empty into the venous system. In consequence of their similarity to the venous system, lymphatic vessels are heir to many of the abnormalities that affect veins. In the extremities there are two separate sets of lymph channels, those of the superficial tissues and those of the deep tissues. In the leg, the superficial ones follow the great and small saphenous veins and communicate with the deep vessels only in the popliteal and groin areas.

Lymphedema is most common in the lower extremity due to the upright posture and the frequent anomalies of the vessel walls and valves which occur. In this respect, the parallel with the venous system is marked, one producing lymphedema and the other varicose veins. Any abnormality that results in lymphatic obstruction or stasis can result in lymphedema. Such abnormalities are manifested mainly in the superficial lymphatics because of the lack of support in the subcutaneous tissues. These derangements include congenital weakness of lymphatic walls and valves, block dissection of lymph nodes and channels, x-ray obliteration of these channels, or their occlusion by neoplastic cells or fibrosis following multiple waves of lymphangitis and lymphadenitis. This occlusion and subsequent stasis result in dilatation of the distal lymph spaces to all degrees from mild swelling to the huge leg of elephantiasis. The collection of lymph in numerous dilated lymph channels in an extremity results in gradually progressing fibrosis as the high protein content of the lymph is a powerful stimulant to fibroblastic proliferation. This fibrosis in an extreme degree produces the

warty excrescences, the thickened inelastic skin, and doughy subcutaneous tissue of the elephantine leg seen in long-standing lymphedema. Infection in this static lymph is also a frequent accompaniment, the streptococcus being the most common organism. Recurrent attacks of cellulitis develop, each of which causes further lymphatic obstruction by its associated lymphangitis and lymphadenitis.

Lymphedema Praecox

This is a variety of lymphedema of the leg and rarely of the arm, which comes on most frequently about the time of puberty but may be seen either earlier or later than this period. Females are more commonly affected

Fig. 530 -- Lymphedema praecox, left leg, in woman aged 20 years

than males. A gradual enlargement of one leg, and possibly later the other, occurs beginning in the foot and ankle and slowly progressing up the leg. The origin is probably analogous to that of varicose veins where a congenital deficiency of the lymphatic system is present involving the lymph valves and possibly the vessel walls. These defective ves-

sels gradually fail to function normally, and dilatation of the lymph vessels to lymph sacs occurs in the most dependent part of the limb. Lymph stasis with enlargement of the limb occurs, this enlargement originally disappearing with elevation of the limb, but later, due to the increased lymphatic enlargement and the accompanying fibrosis, the enlargement only partially subsides on elevation. The patient originally reports for cosmetic reasons, but later complains of tiredness, heaviness, and aching of the enlarged leg. Subsequent waves of erysipeloid-like inflammation of this lymph-soaked tissue may result

Obstructive Lymphedema

Actual occlusion of lymphatic pathways can be produced in the various ways mentioned above. The degree of lymphedema will depend on the extent of this obliteration and resembles the hereditary variety in being confined to the skin and subcutaneous tissue. The swollen arm after radical mastectomy for carcinoma is the result of lymphatic vessel obliteration by carcinoma, chronic infection, x-ray, or radical removal of the pathways, whereas a swollen leg is a late complication of extension of carcinoma of the cervix for the same reasons. However, surgical removal of lymphatic pathways seldom produces the degree of edema seen in the stenosing lesions caused by cancer or infection.

One of the more common causes of lymphedema of the acquired type is a stenosing lymphangitis and lymphadenitis, the result of multiple attacks of lymphangitis usually produced by the streptococcus. The history of such a case is of many attacks of erysipeloid infection in the extremity associated with chills, fever, and general malaise. Each attack is followed by increasing degrees of lymphedema in the limb. This chronically edematous limb appears to harbor the offending organism in a quiescent form between attacks, and the infection is reactivated by more than usual overuse of the leg. This variety of lymphatic stenosis leads to the immense legs of elephantiasis. The word *elephantiasis* is purely a descriptive term and does not denote the etiology. In tropical climates elephantiasis is more common due to the filaria *Bancrofti* which settle mainly in lymph channels and nodes and set up a chronic irritation (frequently in association with the streptococcus) and so produce an extreme degree of lymphatic occlusion.

Swelling of an extremity due to lymphedema has several characteristics. The enlargement is usually unilateral and the swelling subsides only slightly on recumbency in the well-established case. The extremity is whitish in color and the edema is doughy and pits only on prolonged pressure. Varicose veins are absent and there is no history of previous involvement of the deep venous system. The arterial circulation is normal. The symptoms

Fig 331—Lymphedema praecox in man aged 26 years

Milroy's disease is almost identical to lymphedema praecox, but, to conform with the original description of Milroy, it must be both hereditary as well as congenital and therefore present in other members of the same family.

Fig 532—Severe degree of elephantiasis resulting from chronic stenosing lymphangitis and lymphadenitis

Fig 533 Elephantiasis resulting from multiple previous attacks of leg erysipelas and associated lymphatic blockage

Fig 534—Konolet procedure for severe degrees of lymphedema

are those due to the result of the increased size and weight of the limb.

No reliable method has yet been devised to compensate for blockage of the lymphatic return. Consequently treatment is mainly palliative and consists, in the early stages, of elevation of the limb as much as possible and the wearing of compression bandages, the best being a strong elastic stocking or strong elastic or rubber bandage. If the degree of swelling is great and is not controlled by conservative measures, then surgical therapy is indicated. This consists of the Kondoleon procedure and its modifications which remove as much as possible of the lymph-soaked skin, subcutaneous tissue, and deep fascia of the limb. This can usually be done in two or three stages to complete the circumference of the leg. The original plan in this procedure was to establish a communication between the superficial and deep lymphatics whereby the former could drain into the latter by the development of new channels made possible by removal of the deep fascia. However, the major benefit probably results from the mechanical removal of the lymphedematous tissue. Following this method, a strong elastic stocking must still be worn to prevent swelling, as the original reason for the blockage still persists.

Chapter 35

Amputations

Josephus C. Luke, M.D

It is a distressing fact that despite the recent advances in surgical diagnosis and treatment, the number of limbs requiring amputation is increasing rather than decreasing. The reasons for this are those of the changing modern life with its high degree of mechanization, and its increased life span allowing for a greater frequency of the circulatory ailments of advancing age, as well as two destructive world wars in the first half of this century. Modern surgery has saved many lives in the amputated group, increasing the number of amputees, but has failed in most instances in devising means of resuscitating an ischemic limb. Therefore the need for amputation arises sufficiently often that every surgeon should be completely familiar with the indications and technique

INDICATIONS FOR AMPUTATION

Trauma.—The only true indication for amputation following injury is irreparable damage to the blood supply to the limb and development of complete ischemia of the distal part. Such an injury is usually associated with major nerve damage and multiple fractures.

Arterial Occlusion.—As mentioned previously, the most common indication in civilian life is occlusive arterial disease. The increasing age of the population and the prevalence of arteriosclerosis with or without diabetes necessitate the removal of many limbs because of gangrene. However, in the past 5 years the

increasing use of arteriography has demonstrated many cases where the employment of arterial grafts has saved legs from major amputation. Buerger's disease, frostbite, acute arterial spasm, acute arterial thrombosis, and embolism are less common conditions leading to the same result.

Infection.—It is rare in this era of antibiotics for a limb to be sacrificed because of acute or chronic infection. The only exception is the case of widespread gas gangrene not localized to a single group of muscles, and it is not too much to hope that this type of infection will soon be controlled by new chemotherapeutic agents.

Malignancy.—Amputation of the limb well above the lesion is still the chief method of therapy in sarcoma involving the extremity.

Deformity and Uselessness.—Amputation for these reasons is becoming less and less practiced because of the improvement in orthopedic methods and the use of superior orthopedic appliances. This cause finds its greatest frequency in the removal of useless fingers and toes.

SELECTION OF LEVEL OF AMPUTATION

Where amputation is necessary following acute trauma, as much of the limb as possible should be saved. This means that amputation is carried out at the upper limit of the site of trauma. This should be done regardless of

whether the stump is going to be final or require revision. This rule is even more important in battle than in civilian casualties, because, in the latter group, continuous uninterrupted treatment is possible. The reason for this selection of amputation level is that contamination or actual infection is always associated with open wounds and hence the original amputation level is unlikely to be a properly healed wound, especially if done by the guillotine method. An unsightly or unsuitable stump can always be revised at leisure when the initial wounds have soundly healed.

The same ruling applies in cases of frostbite when the gangrene is always more extensive on the surface than in the deeper tissues. Extreme conservatism is indicated to allow a proper line of demarcation to develop. After the dead tissue is removed, the use of suitable skin grafts will save many a foot or hand which originally appeared doomed.

In those cases where amputation is indicated because of deficient blood supply, the result of main artery occlusion, no hard and fast rules can be laid down as to the proper level of amputation. The fact should be kept in mind that amputation is being done for an arterial lesion which is usually progressive and that a successful low amputation may break down months hence because of progression of the disease. This observation applies especially to Buerger's disease. Another point to be remembered is that a lower level stump, though healed, may not be sufficiently supplied with blood to withstand the trauma incident to wearing an artificial limb. Each case is individual, and a careful preoperative study is necessary to determine the efficiency of the existing collateral flow and to ascertain whether this flow can be improved by suitable measures.

It is our practice to carry out the following investigations prior to every amputation indicated because of occlusive arterial disease. Palpation of the pedal and leg arteries is of extreme importance, because it can be stated somewhat dogmatically that primary intention healing (in the absence of infection) will take place after toe amputations if the dorsalis pedis and posterior tibial arteries are felt to pulsate and almost invariably if only one of

the two is actively functioning. Similar findings apply to a transmetatarsal amputation. Healing of a below knee site of election amputation will take place when the popliteal artery is found to be patent, and a good result will follow a lower third of thigh amputation when the common femoral artery is patent.

Frequently a lower amputation can be done successfully in the absence of the above criteria where it can be shown by sympathetic nerve block that the circulation at the proposed amputation level is capable of further dilatation, this being indicated by increased skin temperature readings. Where such improvement is seen, a lumbar sympathectomy done at the time of amputation will ensure a successful lower level of amputation. When infection is associated with the gangrene, a marked local inflammatory response will indicate good collateral circulation and aid in the decision for a minor amputation. The lack of chronic ischemic changes in the soft tissues of the foot also indicates an adequate set of collateral vessels. The histamine flare test and the use of intravenous fluorescein are aids in the determination of the level of adequate collateral circulation and therefore successful healing. Arteriography is also indicated in the selection of those cases suitable for the use of arterial grafts.

In gas gangrene, amputation levels should be above the area of visible diseased tissue. If, at operation, certain muscle groups are found to be involved higher than was anticipated, these groups can be excised and so allow for a longer stump than otherwise would be the case.

In limb sarcoma, the level should be as high as is practicable in order to reduce the possibility of further extension, but it is unfortunately too common that distant metastases have already occurred via the blood stream before amputation is done. A mid-thigh amputation is indicated for growths involving the foot and lower leg or hip disarticulation in tumors of the lower femur. The same levels apply to the upper extremity and a forequarter amputation should be carried out for the neoplasms involving the shoulder region or hind-quarter ablation in those involving the hip area.

REFRIGERATION ANESTHESIA FOR AMPUTATIONS

The use of refrigeration as the complete anesthetic for a limb amputation is occasionally indicated. The person concerned is usually elderly, diabetic, and in poor general condition, coming from a slum district where his previous medical attention has been sketchy or nonexistent. His diabetes has been out of control and becomes more so in association with the severe infection of the foot and leg. He is semicomatose, irrational, and running a high fever. Local examination reveals a blue, foul-smelling, swollen, crepitant foot and leg, and it is obvious that this leg will result in his death from anaerobic infection if not soon removed. He will not stand a general or spinal anesthetic, and time will not allow much in the way of expectant treatment.

The leg to the upper thigh is encased in chopped ice to which salt has been added, and supportive intravenous and diabetic care is commenced. After 2 hours a tourniquet is applied to the thigh just distal to the upper refrigeration level, and the refrigeration is continued. One hour later painless low thigh amputation can be performed. Occasionally a slight spasm is felt by the patient when the sciatic nerve is severed, but otherwise the operation is painless and not shock producing.

The disadvantages to this form of anesthesia are the delay in wound healing due to prolonged tissue cooling and the increased incidence of wound infection, but it is undoubtedly lifesaving in the occasional indicated case.

LOWER EXTREMITY AMPUTATIONS

Toes

Toe amputations are indicated chiefly for deformity, trauma, or deficient circulation. Removal of part of the toe should be reserved for the first two indications mentioned and is done, if possible, by a long plantar and short dorsal flap. Circulatory ailments demand removal of the complete toe; this is carried out by an elliptical incision with lateral flaps. The big toe is the most important one, being an essential factor in proper walking and bal-

Fig. 535—Amputation of toes

ance, and consequently every attempt should be made to conserve as much of this toe as possible.

Transmetatarsal Amputation

Transmetatarsal amputation is frequently used in severe crushing trauma to the forefoot and in those cases of peripheral arterial disease where preoperative tests indicate that healing of or gangrenous toes indicate that healing will likely occur at this level. This amputation has supplanted the time-honored Lisfranc and Chopart types where, in the former, disarticulation of the tarsometatarsal joints was done and, in the latter, the foot was removed by section through the midtarsal joint. In the transmetatarsal variety, a longer plantar than dorsal flap is fashioned because of the thinness of the soft tissues on the dorsum. This applies to cases done because of trauma or occlusive arterial disease and is the only exception to the dictum that equal flaps are indicated when amputation is done for arterial occlusion. The metatarsals are sawn through as close to their bases as possible and all loose tendons are excised. The flaps include skin, subcutaneous

Fig. 536—Transmetatarsal amputation

tissue, muscle, and fascia. The only disadvantages to this operation are the interference with balance of this foot and the tendency of the foot to inversion resulting from pull of the tibialis anticus attachment

Syme's Amputation

The only advantage of Syme's amputation over a site of election removal is that end weight-bearing can be obtained with almost the full length of the leg. However, a prosthesis must be worn for walking and it is of necessity an unsightly one with a bulbous ankle and lower leg corset, making it unuitable for women. This amputation is absolutely contraindicated in occlusive arterial disease because of the poor blood supply to the long plantar flap, and therefore it is used only in

Fig 537—Syme's amputation

cases of trauma. During World War I, the greatest number of Syme's amputations were performed, but the majority of these had to be reamputated at the site of election because of painful or ulcerated stump. However, it should be said that many Syme's amputations have secured lasting excellent service, and it is claimed by the proponents of this type of amputation that the poor results are subsequent to improper selection of cases or incorrect surgical technique.

The tibia and fibula are divided just above the ankle joint through a transverse incision passing anterior to the ankle, and a long plantar flap including all the soft tissues of the heel is swung forward to cover the bone ends and to become the end-bearing surface

Site of Election

This level is probably the most useful in all respects for a leg amputation. It allows a functioning knee joint, and the prosthesis is easily worn and gives a good cosmetic result. Unfortunately, it has a limited application in cases of arterial disease because of the attenuated blood supply below the knee, but the occasional successful result follows a careful preoperative evaluation as outlined in the paragraph on selection of amputation levels.

Fig 538—Site of election amputation

It has its greatest usefulness in cases of severe foot trauma. However, the prosthesis must be carefully fitted and the skin over the tibial end must be movable to prevent the frequent complication of pressure sores over this area.

The length of the stump should be measured from the level of the insertion of the hamstring muscles on the tibia and fibula. Between 5-7" of tibia is the ideal, but a useful

stump can be obtained as short as 2". Less than this makes for great difficulty in having the below-knee section activate the prosthesis. When the amputation level is less than 3" of tibia, it is preferable to excise the entire fibular fragment. This prevents springing of the fibula away from the tibia and the more successful achievement of a conical stump. In traumatic cases a longer anterior than posterior flap is cut, but in amputations due to

long anterior and short posterior flaps make for circulatory troubles in the longer flap, resulting occasionally in sloughing of the edges and consequently a delay in healing. Bony union between the cut surface of the patella and the cut distal end of the femur in the Stokes-Griffith type sometimes fails to occur, and in all types the stump end is bulbous due to the

Fig 539—Recent below-knee amputation because of gangrene of the foot due to Burger's disease

arterial disease, equal flaps are the rule. These flaps as in all amputations, should be slightly larger than the diameter of the limb.

End-Bearing Amputations at the Knee

With the improvement in the construction of artificial limbs, the necessity of end-bearing stumps for proper walking is becoming markedly diminished. Although eminently satisfactory as a functioning stump, this type of amputation has several disadvantages. The

Fig 540—Stokes-Griffith amputation

Fig 541—Previous left midhigh amputation under refrigeration anesthesia and recent right below-knee amputation in a case of diabetic gangrene

flare of the remaining portion of the condyles. This fact added to the longer thigh resulting from the artificial knee joint makes this type of amputation unpopular with the limb maker.

The two main varieties of end bearing above-knee amputations are the Stokes Gritti and the Callander types. In the former, the femur is divided at the upper level of the condyles and the articular surface of the patella is removed. A long anterior and a short posterior flap are necessary. The patella is retained in the anterior flap and the bare surface of the patella is fixed to the cut surface of the femur. Bony union between the two is a necessity. The Callander type is somewhat the same except that the patella is removed from the quadriceps expansion and the cut end of the femur is covered by this expansion.

Thigh Amputations

It is the opinion of most surgeons interested in peripheral vascular disease that when a good site of election amputation is not feasible, the lower third of the thigh is the next best choice. At this level the arterial supply is adequate, long flaps are unnecessary, and wound healing is thereby improved. A good functioning prosthesis can be easily fitted. The majority of amputations done for the complications of obliterative arterial disease will be done at this level.

The optimum level is $2\frac{1}{2}$ " above the knee joint, but an adequate stump is obtained from the middle of the middle third of the femur to this level. Equal flaps can be used, but a slightly longer anterior one is preferable. The subsequent shortening of the stronger hamstring muscles pulls the suture line posteriorly, even when the flaps are initially equal. Suturing of the cut muscle over the bone end is not advisable when it is likely that a prosthesis will be worn because the resulting bulky end of the stump makes for difficulty in fitting a proper socket. However, in patients who are unlikely to wear an artificial limb, this point has advantages in cushioning the stump end. The author prefers to cut the muscles at the level of bone section and retain only the deep fascia and a small amount of muscle with the skin flaps. The nerves are cut as high as possible to keep them clear of the scar. The

sciatic is the only one which should be ligated at the time of division because of the artery that runs within.

The least amount of thigh possible necessary to guide a prosthesis is 6" from the great trochanter, consequently every effort should be made to achieve this length. If a higher amputation is necessary because of trauma or malignant disease, the head and neck of the femur should be retained to preserve hip contour. This is more desirable and is easier than hip disarticulation.

Fig. 342—Supracondylar amputation.

Hindquarter Amputation (Interinnomino-Abdominal)

This heroic amputation is indicated only in primary malignancies involving the head and neck of the femur or the pelvic bones on one side. It consists of removal of the limb and half the pelvic girdle, after division of the symphysis pubis and ligation of the common iliac vessels on that side. A portion of the sacrum may need removal if the position of

the tumor so demands. The cure rate is understandably low when the operation is done for osteogenic sarcoma but is better in chondrosarcoma and fibrosarcoma.

UPPER EXTREMITY AMPUTATIONS

Fingers

Whether a finger should be amputated after trauma of a crushing type depends upon many individual factors. No hard and fast rule can be laid down, but, in general, it should be

Fig 543 - Amputation of fingers

said that if there is any possibility of obtaining a moderately functioning finger, then conservatism is indicated. A poor result can always have a subsequent amputation. Because of the frequency of poor results, most large hospitals have organized a Hand Group, who, with their teamwork, especially between the physiotherapist and traumatic and plastic surgeons, achieve better results than those usually obtained. It is in the segregation of these cases under the care of such a well-trained group that the hope of improvement in results rests.

In general, it can be said that amputation is indicated when, due to injury, pain, or sepsis, the finger becomes a menace to the individual, it is useless or actively in the way, or it interferes with the use of the hand. (See also Amputating Injuries of the Hand and Figs. 641-643, Chapter 39.)

Following are other points to be kept in mind:

1. The working man requires a strong mobile hand. Stiff fingers interfere with his manual labor and must be avoided. The cosmetic factor is of secondary importance. Therefore, in general, immediate finger amputation is more often indicated in trauma than are prolonged plastic procedures.

2. In children, the most conservative approach is taken because of their wonderful powers of functional restoration.

3. In men and women of the executive type, the cosmetic factor is most important and great strength is a secondary consideration.

4. Tendons should never be sutured over the amputated ends of fingers because this interferes with the function of the other digits.

5. When amputation takes place through joints, the cartilage should be removed to prevent a bulbous and sensitive stump. Cartilage is also more subject to infection, fistula, and sequestration than bone.

6. If amputation is in the region of the nail bed, the nail matrix should be totally removed to prevent the development of horny nail growths.

The level of removal of a damaged digit is open to considerable controversy, and it should be emphasized that the length of a finger should not be sacrificed to obtain skin flaps because such skin deficiencies can be easily remedied by skin grafting. In general, the following statements are widely accepted:

The thumb is by far the most important digit, but it requires parts of the other digits for proper opposition. Therefore the most conservative attitude is required in treatment of its injuries, all possible length is preserved, using skin grafts. All possible length of the other damaged fingers is also indicated for the best possible opposition. (See also Fig. 641.)

The index finger is next in importance. Traumatic amputation of the tip is best treated

by skin grafting to a pedicled graft lifted from the skin of the thenar eminence, or pectoral region, or by a split-thickness skin graft. If more than the distal one and one half phalanges are destroyed, amputation is best through the metacarpal to give optimum cosmetic appearances. This latter point applies only when the thumb is undamaged and should be considered only as a secondary procedure in the laborer.

The middle finger can be amputated at any point because any length of stump adds strength to the hand. Therefore, in the manual worker, conserve as much as possible of all phalanges. In the white collar worker who has lost the majority of this finger, it is probably wise to remove the entire finger and the complete metacarpal. This allows the index finger to take over the function of the middle and gives a much better cosmetic result.

The ring finger can be treated on much the same lines as the middle.

The little finger is of least importance. Amputations are successful at any level, but when most of the finger is destroyed, the head and most of the shaft of the metacarpal should be removed to give best cosmetic results. The metacarpal head is best preserved in the laborer.

Forearm Amputations

Forearm amputations are indicated mostly as a result of severe trauma. Occlusive arterial disease rarely involves the upper extremity to the point of needing amputation. Weight-bearing and strain on the stump in the prosthesis are not factors to be reckoned with, consequently upper extremity amputations rarely are heir to later complications. Equal flaps are therefore indicated. The optimum levels are not more than 7" from the olecranon to a minimum length of 1" beyond the insertion of the biceps tendon. Less than this amount leaves insufficient length for the forearm stump to control the artificial elbow. A disarticulation at the wrist has little to recommend it and is inferior to a 7" forearm stump.

Upper Arm Amputations

The same observations as in the forearm apply to the upper arm. The optimum level

is 8" from the acromion process, and the minimum functioning stump is 1" from the anterior fold of the axilla.

Forequarter Amputation (Interscapulothoracic)

The indications for this procedure are the same as in the hindquarter removal. The arm, including the scapula and all or most of the clavicle, is removed along with the associated muscles, axillary fat, and nodes. The subclavian vessels must be tied early in the operation and the brachial plexus divided.

Fig. 341—Forequarter amputation.

AFTERCARE OF AMPUTATIONS

It is the surgeon's responsibility not only to do the amputation and assure a good convalescence but also to be certain that the patient is physically and mentally prepared for his artificial limb. Loss of a limb is a great psychic shock to any individual, and the ability of the patient to adapt himself to his artificial limb will depend on his mental attitude toward it. The surgeon can do a great deal in promoting a healthy mental attitude of his patient toward his disability. Early postoperative mobility, occupational therapy, moving pictures of the activities of other amputees, and personal visits to the patient by other adapted individuals with loss of a limb will be a big boost to morale. Certain patients, however, never are capable of wearing a prosthesis, and expensive and misguided efforts in obtaining a limb for such a person should be discouraged. Many persons in the 6th, 7th, or 8th decade never acquire the balance or will power to use

crutches successfully, let alone learn to use an artificial leg. Such patients have usually been bedridden for months before amputation is finally done. Their musculature has wasted and their morale is poor. In most of these patients the remaining limb is also involved by arterial disease, and in about 30% its amputation is necessary within 3 years after the initial one.

Despite the possibility that an artificial limb may never be worn, all amputations should be treated postoperatively as though that possibility did not exist. The cardinal principles of aftercare of the stump are as follows.

- 1 Shaping of the stump by bandaging to control edema and prepare the limb for the prosthesis
- 2 Exercise of the stump to enable the amputee to use the artificial limb adequately
- 3 Prevention of stump contractures

CINEPLASTIC AMPUTATIONS

The plan of employing individual muscles or groups of muscles to activate a functioning part of the prosthesis was first conceived by Vanghetti in Italy at the close of the last century. A slow development of this technique has taken place but has not been widely accepted because of the inability of the limb maker to produce an artificial limb capable of properly utilizing this surgical advance. However, since the close of World War II, renewed interest has been aroused by the development of improved prostheses, and it is likely that the usefulness of this method will be more appreciated and more widely used.

The upper limb only is suitable for this modification because the finer movements achieved in an artificial hand are unnecessary in the leg. In general, the technique consists of utilization of a muscle or agonistic group of muscles to act on a skin tunnel around which the appropriate tendons have been fixed. This action is transmitted to a rod in the skin tunnel which is connected to activate the artificial fingers (thumb and index). Powerful and delicate voluntary movements can be achieved, allowing for the grasp of any object from that of a match to a hammer. The formation of the so-called "motor" loop can be accomplished at the time of the initial amputation, when infection is not a possibility,

or following the initial amputation. However, if done later, it must be ascertained that the individual muscle has sufficient length and still is an active contractile unit. Intensive training and use of the utilized muscles is a most important postoperative measure.

THE PROSTHESIS

No two amputations are of exact similarity even though of the same type, hence each limb has to be made to order. The correct artificial limb should be applied as soon as possible, but in most cases the stump is not adequately shaped before 4 months. The wearing of temporary "peg legs" or pylons is inadvisable because they lead to incorrect walking habits. Later corrections to the initial socket are always necessary as continued shrinkage occurs. Good fit, lightness, durability, and good repair service from the limb maker are essential points in an artificial limb. The most recent advance in limb fitting is the further development of the original German idea of the suction socket for thigh amputation. In these the stump is held in a close-fitting bucket in which a negative pressure is produced by exhausting the air in the socket through a distal valve when the stump is inserted. This allows more natural walking and dispenses with the pelvic band necessary in the conventional types. Cases suitable for this design must, however, be carefully chosen and must not be those done for occlusive arterial disease.

Chapter 36

Fractures

H. Fred Moseley, DM

A *fracture* may be defined as a breach in the continuity of a bone which is complete or incomplete. Fractures are of many types, depending on the mode of classification:

A Traumatic—when due to an adequate force of:

- 1 Direct violence
- 2 Indirect violence
- 3 Muscular violence

B Pathologic—when largely due to disease in the bone caused by:

- 1 Congenital defects, *fragilitas ossium*, pseudoarthrosis of tibia
- 2 Metabolic errors, rickets
- 3 Generalized bone disease, Paget's disease, hyperparathyroidism
- 4 Generalized osteoporosis, old age, invalidism
- 5 Local inflammation, osteomyelitis
- 6 Neoplasm; benign or malignant

Fractures may be classified according to the absence or presence of a communicating skin wound into (1) closed (simple) and (2) open (compound).

The use of the word *simple* is probably misleading and should be replaced by the word *closed*. Very few fractures are simple to understand or treat. It is well to realize that a patient with a fractured tibia is best regarded as a *patient with a fractured leg* and the problem must be so assessed and treated. Too much emphasis must not be placed on the bone alone; adequate attention must be

given to the soft tissues of the affected part and the patient as a whole in relation to his work and family.

An *open* or *compound* fracture is one in which a wound in the skin and soft parts places the environment in communication with the fracture site.

There are two types of open fracture:

1. Direct—in which the direct violence compounds the fracture from without
- 2 Indirect—in which the indirect violence causes the fractured fragments to compound the soft tissues from within

Birth fractures occur in relation to the mechanics of parturition and may involve any of the long bones of the upper or lower limbs. The bones most commonly fractured are the humerus, clavicle, and femur. Epiphyseal displacements occur in relation to the lower end of the femur and both upper and lower ends of the humerus.

Greenstick fractures occur in children before puberty when the bones are elastic like green twigs and bend rather than break. When the fracture separates at the epiphyseal plate with or without a fragment of metaphysis, the injury is called an epiphyseal separation.

A sprain fracture results from a joint displacement where the ligament avulses its bony attachment in place of rupturing its fibers.

Fractures may be closed or open, complete or incomplete, or complicated by associated lesions of muscle, nerve, or blood vessels.

Fig 545—Stages in the healing of fractures (After Utist)

Fig 546—X-ray of clinical union

REPAIR OF FRACTURES

The process of repair follows immediately the occurrence of fracture. A hematoma develops around the broken fragments and injured soft tissues. Traumatic inflammation ensues with hyperemia, edema, resultant swelling, heat, local pain, and tenderness.

The fracture hematoma is widely considered the basis on which the healing process develops. The hematoma is replaced by granulation tissue from which callus, the healing cement of bone, arises. Into this callus, calcium and phosphate ions are precipitated from

periosteal and endosteal aspects, which permits the *permanent* or *definitive* bone to be laid down later in orderly fashion between the compact surfaces.

Clinical union may be said to be present when the fractured bone will move as a unit without pain or local tenderness. At this stage, guarded and graduated stresses and strains will accelerate the further consolidation of the healing by laying down the final architecture according to Wolff's law. As the permanent callus gains strength, the temporary callus absorbs except where necessary as a permanent

Fig. 547.—X-rays showing consolidation of fractured tibia sustained 6 years previously and also a fresh fracture-dislocation of the ankle.

the blood and from mobilized minerals of the bone ends. The two forces directing the course of repair are the vital activities of the osteoblasts in the early and late stages and, after a certain point, functional stresses and strains. The circulatory status of the healing tissues is very important.

The general method followed by Nature is to lay down first a *temporary* scaffold on the

buttress. X-ray, however, at this stage will not show bony trabeculae crossing the fracture line, and the line will still be visible.

Consolidation or final union requires a much longer period and is present when the x-ray shows the restoration of normal architecture with loss of the fracture line and trabeculation across this area completed. Consolidation or final union is therefore today an

x-ray interpretation. Function may be possible for months before this stage is finally reached in fractures of the long bones.

CLINICAL PICTURE

Patients with fractures present a variable picture, from the minor complaints that might suggest merely a sprain or bruise of bone to the severe symptoms of shock seen in open, complicated, or multiple fractures. All require a careful general as well as local examination, bearing in mind the possibility of severe internal injuries in the transport accidents of this age.

In fractures involving the limbs, a careful study of the circulatory and neurologic status must be made. This is especially true in open fractures and fractures associated with marked displacement or dislocation.

In evaluating the clinical picture, the following factors must be considered:

History of Accident.—A detailed account of the accident must be obtained. The exact hour, the method of handling at the time, the manner of transport to hospital, time of arrival in the ward, and operating room are significant from a medical and possibly a legal point of view. The severity of the injury gives an approximation as to what may be expected in bodily damage.

Local Symptoms and Signs of Fracture.—

1. Pain—exquisite pain is felt in the region of the fracture. The muscles are in spasm and any movement augments discomfort.

2. Tenderness is noted on palpation of the fracture site.

3. Swelling may be present from extravasation of blood or from displacement of the bone ends.

4. Deformity occurs in the presence of angulation or overlap of the bone fragments.

5. Excessive mobility and bony crepitus will be noted on examination of a complete fracture.

6. There is loss of function.

7. X-ray examination is imperative and gives information regarding the exact injuries and displacement of the bony skeleton. It must always, however, be considered as an accessory to accurate clinical observation of the patient, although elicitation of crepitus and painful examination are rendered unnecessary

EMERGENCY TREATMENT

General.—Therapeutic measures will be determined by the conditions under which the patient is first seen. If attended at the site of the accident, assessment of the severity of the injuries is of prime importance as this will decide the urgency of treatment. In most cases, the ready accessibility of hospital facilities and the rapid means of transportation available permit the delay in definitive measures, such as transfusions, antibiotics, and antitetanic serum, until the patient has been admitted. The patient should be warmly wrapped in blankets and moved with great care. Morphine should be given to diminish pain and psychic trauma. In cases of severe blood loss and shock, transfusions can be started in the ambulance.

Local.—The most important treatment at the site of the accident is to splint the fractured limb securely. All unnecessary movements should be avoided. When gross deformity is present or when the fractured bone end projects from an open wound, it is best to reduce the deformity and replace the projecting bone end using traction and counter-traction. This will improve the circulation to the peripheral part of the limb, and later operative treatment will include removal of the contamination by wound cleansing and excision of devitalized tissue. The wound should be temporarily covered with the cleanest dressing available. When hemorrhage is present, a pressure dressing is applied and the limb elevated. A tourniquet is rarely necessary. If used it should be released every 15 minutes, and only pressure adequate to obliterate the pulse should be applied.

The splints employed will depend on the available materials. Plaster of Paris and Cramer wire can be readily adapted to the various regions requiring protection. A temporary padded cast can be quickly applied after the fracture has been placed in the best possible alignment. Plaster casts are most valuable as temporary splints for the lower arm, elbow, forearm, and wrist and for the lower leg, ankle, and foot. For the shoulder region and upper arm, an encircling bandage around the arm and chest applied with an axillary pad and sling is a comfortable ar-

3 Swelling may be present from extravasation of blood or from displacement of the bone ends.

4 Deformity occurs in the presence of angulation or overlap of the bone fragments.

5 Excessive mobility and bony crepitus will be noted on examination of a complete fracture.

6 There is loss of function.

7 X-ray examination is imperative and gives information regarding the exact injuries and displacement of the bony skeleton. It must always, however, be considered as an accessory to accurate clinical observation of the patient, although elicitation of crepitus and painful examination are rendered unnecessary.

EMERGENCY TREATMENT

General. Therapeutic measures will be determined by the conditions under which the patient is first seen. If shocked at the site of the accident, assessment of the severity of the injuries is of prime importance as this will decide the urgency of treatment. In most cases, the ready availability of hospital facilities and the rapid means of transportation available permit the delay in definite measures, such as transfusions, antibiotics, and antishock serum, until the patient has been stabilized. The patient should be warmly wrapped in blankets and covered with grease ointment. Morphine should be given to decrease pain and psychic trauma. In cases of severe blood loss and shock, transfusions can be started in the ambulance.

Local.—The most important measure at the site of the accident is to splint the fractured limb securely. All unnecessary movements should be avoided. When gross deformity is present or when the fractured bone end projects from an open wound, it is best to reduce the deformity and replace the projecting bone end using traction and counter-traction. This will improve the circulation to the peripheral part of the limb, and later operative treatment will include removal of the contamination by wound cleaning and excision of devitalized tissue. The wound should be temporarily covered with the cleanest dressing available. When hemorrhage is present, a pressure dressing is applied and the limb elevated. A tourniquet is rarely necessary. If used it should be released every 15 minutes, and only pressure adequate to obliterate the pulse should be applied.

The splints employed will depend on the available materials. Plaster of Paris and Craver wire can be readily adapted to the various regions requiring protection. A temporary padded cast can be quickly applied after the fracture has been placed in the best possible alignment. Plaster casts are most valuable as temporary splints for the lower arm, elbow, forearm, and wrist and for the lower leg, ankle, and foot. For the shoulder region and upper arm, an encircling bandage around the arm and chest applied with an axillary pad and sling is a comfortable ar-

arrangement for transportation. For fractures involving the hip, femur, knee, and upper two thirds of the tibia and fibula, a Thomas splint arranged for fixed traction with a circular bandage of flannel or plaster of Paris is excellent. An alternative method of splinting when transport over long distances is required would be a plaster spica. In cases of fractures of the lower leg, ankle, and foot, the pillow splint is readily applicable. On arrival in hospital, the patient should be prepared for definitive treatment at the earliest moment.

For the emergency treatment and transport of vertebral fractures, see Chapter 11, Neurosurgery, and Chapter 43, Disorders of the Vertebral Column.

ORGANIZATION OF FRACTURE TREATMENT

An organized approach is required to secure uniformly good results in fracture work. The principles of this organization are as follows:

- 1 Segregation of cases
- 2 Uniformity of treatment with standardization of methods and equipment
- 3 Supervision by the same personnel from the initial to final treatment
- 4 In all cases a planned program for each patient; should include physiotherapy, occupational therapy, and general rehabilitation

FUNDAMENTALS OF FRACTURE TREATMENT

The ideal of fracture treatment is to secure the maximum return of function in the minimum time.

Reduction.—Displacements are reduced to their anatomic position if possible.

Immobilization.—The fracture is immobilized by splinting until united.

Protection.—The part is protected during the period between clinical union and consolidation with graduated return to full function.

Functional Treatment of Soft Parts.—From the earliest moment function of the soft parts is encouraged. The patient is made ambulatory at the first opportunity. Return to light work precedes full duty, and rehabilitation should be an essential part of the treatment.

REDUCTION

Reduction means the restoration of the displaced fragments to as near the anatomic position as possible. Perfect reduction is the ideal, but this cannot always be achieved because of the nature of the injured surfaces, the interposition of soft parts, and the later influence of altered muscle pull, splinting, and gravity. For this reason a knowledge of what constitutes adequate reduction is of the greatest importance.

The age of the patient determines the plasticity of the bone. In infants and young children, the healing power of bone is very great, and often fractures uniting in positions of gross displacement will finally in the course of time be reformed to the shape of the normal bone in the area. This quality of bone diminishes rapidly from birth to old age, but at any age this fact should not influence our desire for perfect reduction. It should, however, be recognized that end-to-end reduction for fractures of the femur in the young is undesirable, as overgrowth in the length of the bone usually results. An overlap of $\frac{3}{4}$ " is ideal.

The Site of Fracture.—Fractures in the shafts of the long bones of the upper limb may heal with overlap and sometimes with angulation without gross interference to function of the limb as a whole. One joint may be disorganized by malunion, but the other joints usually increase their range of function to compensate for this defect. Shortening of the limb by 1" or more is not usually obvious. In the lower limb, however, shortening of any degree over $\frac{1}{2}$ " results in inequality of leg length and requires compensation by correction to the shoe. Without this a limp may be present. Any alteration of the normal direction of force through the joints due to angulation is followed by abnormal stresses and strains which, because of the transmission of body weight, lead to wear and tear changes or traumatic arthritis.

If the site of fracture involves the joint surfaces, exact anatomic reduction is required, otherwise the smooth gliding action is lost and, as is found in machinery, rapid deterioration of the mechanism results. Joint injuries frequently require removal of loose fragments of bone in order to prevent the rapid development of traumatic arthritis.

over pulleys balanced by elevation of the foot of the bed, the expression *balanced traction* is employed.

The most common use for continuous traction is in displaced fractures of the thigh or leg. Either the Thomas or Braun splint is used

Fig 349—Well-leg traction

Sometimes traction to the affected extremity can be secured by upward pressure on the normal limb through the sole of the foot, by the use of the parallelogram of forces secured by the Roger Anderson apparatus.

This constitutes the principle of *well-leg traction* employed occasionally for fractures of the upper end of the femur.

Distraction and Impaction.—A variation of traction and countertraction methods where

complicated apparatus is involved is the method of mechanical distraction followed by impaction with the use of external fixation for immobilization. The two sets of apparatus most commonly used are those of Roger Anderson and Stader. This method requires considerable experience for successful use and has not gained great popularity because of this difficulty and the dangers of infected pin holes and joint stiffness.

Operative Reduction.—Operative reduction and the associated internal fixation of fractures were introduced by Lambotte and Lane at the beginning of the century. They were dissatisfied with the clinical results obtained in oblique fractures of the femur and tibia in adult patients. The method was correct, but its application until recent years resulted in serious complications due to infection, poor surgical technique, and foreign body reaction.

The present use of this method has been increased by the following considerations:

1. Improved standards of technique and asepsis on the part of the surgeon, his assistants and associated operating room personnel
2. The prophylactic and curative power of the chemotherapeutic and antibiotic drugs
3. The development of inert metal for plates and screws

It is not the method for all fractures and should be used only in selected cases. Its chief danger is still the fact that it converts the closed into an open fracture and invites disaster if complications ensue.

Indications.—

1. When manipulation will fail or has failed because of (a) interposed soft parts, (b) separation of fragments by muscular contraction—patella—olecranon, (c) delayed treatment with malunion, (d) certain intra-articular fractures
2. When reduction cannot be maintained, oblique fractures of femur, tibia, or femoral neck.
3. In fractures complicated by injury to blood vessels, or nerves, necessitating their exposure

The guiding principle in the reduction of fractures is to employ the correct method, for the correct case, in the correct manner, at the correct time, and to select when possible the nonoperative procedures.

IMMOBILIZATION

Plaster-of-Paris Technique

This constitutes the most useful of the methods for the immobilization of fractures. Since the introduction of the plaster bandage by Mathijsen in 1852, the technique has greatly improved, and today casts are applied in such a way as to preserve the maximum function of the part and to permit early ambulation. The most important principle is to apply the lightest possible splint with the parts held in the positions of optimum function. Excessive weight of cast is to be avoided since the requirement is a patient with an attached splint, not a splint with an attached patient.

Method.—The plaster bandage and slab are the building blocks of the finished cast, and in order to standardize the work it is necessary to have uniform materials.

Uniform bandages and slabs must possess:

- 1 A standard width and length
- 2 A uniform amount of plaster applied to crinoline or mesh
- 3 A standard time for hardening
- 4 A minimum of shrinkage during the process of drying

The plaster may be applied directly to the skin. This is called the *nonpadded* technique popularized by Böhler. Most workers cover the limb with stockinet and place a variable amount of sheet wadding over bony prominences before the plaster is applied. This is the more popular method and is called the *padded technique*. The danger of pressure effects on the skin, circulatory mechanism, or superficial nerves of the part is thereby lessened.

The bandage is immersed in water until the bubbling ceases and is then applied evenly without constriction, taking care to smooth one layer against the other and remove all air spaces. After the cast is applied, hardening may be accelerated by the use of an electric drier or baker. A cast that is lighter, harder, and more resistant to moisture and soiling may be obtained by the use of commercial preparations such as Melmac.

If the cast is applied to a fresh fracture and swelling is expected, the circular cast is split to enable this to occur without danger

to the limb. Elevation of the limb is essential. The patient is taught to contract all muscles possible under the cast and to move all adjacent unsplinted joints. In the upper limb active use of the fingers is most important. The splinted part is carefully observed for 36-48 hours following the application of the cast to see that no complications occur, such as interference with circulation.

Standard Casts.—

Upper Limb.—

Shoulder spica:

- For avulsion fractures of greater tuberosity
- For arthrodesis of the shoulder
- For ruptures of rotator cuff

Hanging cast:

- For fractures of the lower half of shaft of humerus

For fractures around elbow

Sugar tong cast: For fractures of shaft of humerus

Colles' cast: For fractures of lower end of radius

Sugar tong cast: For fractures of radius and ulna

Scaphoid cast: For fractures of scaphoid

Bennett's splint: Traction with cast for Bennett's fracture dislocation

Lower Limb.—

Plaster spica: For fractures of hip or femur

Thigh cast: For fractures of tibia and fibula including unstable ankle fracture-dislocations

Cylinder: For fractures of patella

Below-knee cast: For first and second degree ankle fractures

Spine.—

Cervical collar and Minerva jacket (see Fig. 722): For cervical injuries

Body jacket (see Fig. 723): For lower dorsal and lumbar fractures

Complications.—

1 *Plaster sores* result from continued pressure on the cutaneous tissues overlying bony prominences. The sacral area, anterior iliac crest, malleoli, heel, and bony points around the elbow are the sites most frequently involved. The thin, emaciated patient confined to bed is subject to these sequelae. The lower edge of the cast may cause ulceration of the skin if the limb distal to this point is swollen.

from dependency. Creases on the deep aspect of the cast from movements during the application may cause subsequent skin ulceration. This is especially frequent over the anterior aspect of the ankle.

2. *Circulatory disorders* are prone to occur if the cast is too tight. This may follow immobilization of the recently reduced fracture with subsequent swelling of the limb. Careful attention must be given to the peripheral pulse and cutaneous circulation. Pain and swelling necessitate relief of the constriction by splitting the cast and elevating the part. The cast may predispose to Volkmann's ischemic contracture in elbow injuries or even to gangrene of the distal part where the circulation is completely occluded for too long a period. Sympathetic block is an accessory therapeutic measure to be considered in such cases.

3. *Neurologic lesions* may occur from direct pressure on nerve trunks. The most commonly involved nerve is the peroneal on the neck of the fibula. This may be damaged by the upper edge of a below-knee cast or by pressure from an unpadded area of the hip spica or thigh cast.

4. *Loss of reduction* may result if the cast is applied with too much padding or when the limb is swollen. In both cases the cast loosens in time. This is obviated by avoidance of excessive padding and change of cast on subsidence of edema.

Traction

In cases in which traction has been used to secure reduction, immobilization may be obtained by the use of continued traction. This is especially useful in fractures of the shaft of the femur.

External Fixation

The use of two pin units and connecting bar can be employed for certain cases.

Internal Fixation

This may be accomplished by the externally applied plate, the Smith-Petersen pin, longitudinally placed Kirschner wires, or the intramedullary nail (Kuntscher). Immobiliza-

tion by internal fixation is usually supplemented by a plaster cast until clinical union is obtained.

PROTECTION UNTIL CONSOLIDATION

A considerable interval of time intervenes between clinical union and final consolidation as demonstrated by x-ray examination. In the upper limb, this protection can be secured by graduating the function of the part and avoiding sudden strain or injury. No special apparatus is required.

Fig. 354—Walking caliper (Thomas)

In the lower limb, the protection is secured by graduating weight-bearing through the use of crutches and cane. In fractures of the femur, the Thomas walking caliper is an additional support. In fractures of tibia and fibula the caliper or a plaster cylinder may be worn.

FUNCTIONAL USE OF THE SOFT PARTS

The earliest moment after the initial treatment the patient is informed of the extent of his problem and the injury assessed in relation to his possible time in hospital, absence from home and work, and the economic factors involved. His cooperation both mentally and physically is required for efficient treatment, and this can be secured only if he understands the manner in which he can assist the surgeon. The doctor's main thought must be directed toward the problem of the patient as a whole in relation to his environment, and he must try to fit the treatment of the fractured limb to this pattern.

The greatest benefit is usually rendered by assuring the patient that he will eventually make a good recovery and return to full work, that the period required will be considerably shortened if he will actively contract all muscles of the part even though covered by a plaster cast, that active movements of all unsplinted joints and the constant use of the unsplinted fingers are essential.

Encouragement is given by the physiotherapist who supervises these activities and employs heat, massage, contrast and whirlpool baths together with active exercises in his regime.

For patients requiring prolonged institutional care, occupational therapy will keep the mind occupied and stimulate progress.

At the earliest moment, the patient should be made ambulatory and functional use of the part encouraged. Return to light duties should precede heavy routine work. For patients with Colles' fractures properly splinted, typing, driving a car, and such activities are permitted.

In lower limb fractures, most sedentary occupations can be carried out in a walking cast. In severe injuries in the working class, a period in rehabilitation centers should precede return to full duty.

OPEN FRACTURES

In these cases, the principle is to treat the wound in the soft tissues so as to obviate infection and convert the open into a closed fracture.

This ideal may be possible if the soft tissue damage is not extensive and the patient is seen

within 6-12 hours. In civilian practice, with the use of chemotherapy and antibiotics the percentage of successful closures of such wounds is much higher than in the period preceding 1940. Extensive wounds in military practice are best left open and treated by secondary suture.

The initial treatment requires the general care of the patient and measures directed to combat hemorrhage and shock. Following this, a meticulous cleansing of the wound by excision of devitalized skin, necrotic tissue, fascia, and muscle is performed in the operating room under appropriate anesthesia.

Displaced fractures are reduced and immobilization arranged by internal fixation or by external splinting. The wound is closed, if this is possible without tension, relieving incisions may be necessary; otherwise it is lined and lightly packed with fine mesh gauze. Local antibiotics may be placed in the wound. After 5-7 days the pack is removed and the wound is closed by secondary suture or plastic procedure.

Antibiotics are given systemically for at least 6 days. Antitetanic serum is administered routinely.*

COMPLICATIONS OF FRACTURES

The complications of fractures include the immediate associated lesions together with those disorders that develop later as the result of the original accident. Complications may be classified as *immediate*, *delayed*, or *remote* and may be *general* (systemic) or *local* in character.

Examples

Immediate complications

- 1 Traumatic shock
- 2 Radial nerve paralysis with fractured shaft of humerus

Delayed complications

- 1 Fat embolism which is most common 19-72 hours after the accident
- 2 Volkmann's ischemic contracture

Remote complications

- 1 Recumbency lithiasis from prolonged confinement to bed
- 2 Secondary ulnar paralysis in a case which has developed cubitus valgus as a result of an old fractured lateral humeral condyle with premature synostosis

*Gas gangrene (See section on Surgical Bacteriology and Chemotherapy)

Classification.—

General:

1. Traumatic shock (see Chapter 4, Shock and Blood Transfusion)
2. Pyrexia
3. Crush syndrome
4. Fat embolism (see Chapter 3, Preoperative and Postoperative Care)
5. Pulmonary embolism
6. Recumbency lithiasis (see Chapter 31, Genito-urinary System)
7. Bedridden state, pressure sores, hypostatic pneumonia

Local

- 1 Injury to adjacent joints (see Chapter 37, Joints)
 - Joint adhesions and stiffness
 - Synovitis
 - Dislocations
 - Traumatic arthritis
- 2 Complications of union
 - Nonunion
 - Delayed union
 - Malunion
 - Aseptic necrosis
- 3 Injury to muscles, tendons, ligaments, and periosteum adjacent to fracture site, e.g., myositis ossificans, rupture of extensor pollicis longus tendon after a Colles' fracture
- 4 Injury to nerves (see Chapter 11, Neurosurgery), such injuries usually contusions and rarely ruptures
 - Upper limb
 - a Brachial plexus—Fractured clavicle Fracture dislocation of shoulder
 - b Axillary nerve—Dislocation of shoulder
 - c Radial nerve—Fracture of humerus
 - d Ulnar nerve—Fracture dislocation of elbow
 - e Median and ulnar nerves—Involved in Volkmann's contracture
 - f Median nerve—Irritated by anterior dislocation of the semilunar bone
 - g Digital nerves—In compound injuries of fingers
 - Lower limb
 - a Sciatic nerve—In posterior dislocation of hip
 - b Peroneal nerve—In fractures of neck of fibula, from pressure of plaster cast
- 5 Injury to blood vessels (see Chapter 33, Peripheral Vascular Diseases)
 - Arteries
 - a Traumatic arterial spasm leading to Volkmann's ischemic contracture or even gangrene
 - b Arteriovenous aneurysm
 - c Complete rupture
 - Veins Hematoma—thrombosis
 - Vasomotor imbalance—Sudeck's atrophy
- 6 Compound injuries (see Chapter 41, Infection of Bones)
 - Infection leading to osteomyelitis

Factors Predisposing to Joint Stiffness

1. Interference with circulation to the distal part of the limb caused by splinting in a faulty position. For example, splinting a case of Colles' fracture in forced volar flexion in the older patient results in swelling of the hand and fingers with subsequent stiffness.
- 2 Excessive or prolonged traction through joints such as the knee or fingers.
3. Reactionary edema after injury to a limb.
4. Effusions into joints often result from ligamentous damage
5. Infections near joints, e.g., skeletal traction pin sinuses
6. Passive stretchings
- 7 Disuse atrophy.
8. Reflex autonomic imbalance.

Treatment.—

Prophylactic.—

1. Maintenance of functional activity of all unsplinted joints and active contractions of all muscles under casts.
2. Avoidance of splinting in positions other than those of function
3. Use of traction through joints of minimal required force, and only for periods absolutely necessary.
4. Elastic support to prevent edema.
5. Use of sympathetic block to overcome autonomic imbalance.

Curative—When stiffness has developed, the appropriate use of heat, massage, and active exercises is the basis of treatment. The range of movement must be measured and the progress charted to ascertain whether the therapy is beneficial. Forced manipulations and passive stretchings are best avoided.

DELAYED UNION AND NONUNION OF FRACTURES

The time required for the union of a fracture depends on many factors. It is therefore most difficult to define accurately when such healing is too slow.

Delayed union may be said to occur when the average time for the particular fracture has been passed and the x-ray shows decalcification and widening of the fracture line.

Nonunion is present when there is movement at the fracture line when tested clinically and the x-ray shows sclerosis of the bone ends

Factors Which Tend to Delayed Union and Nonunion.—

1. **Inadequate reduction** In certain fractures such as those of the patella or olecranon the fragments may be widely separated. Interposition of soft tissues between the bone ends is frequently found. This may be avulsed periosteum, as found in fractures of the medial malleolus and neck of the femur, or muscle, as in the case of fractures of the shafts of long bones. Failure to oppose and fix the frag-

3. **Excessive traction.** This causes a gap wider than the osteoblasts can readily bridge.

4. **Poor circulation to the fractured fragments,** especially if aseptic necrosis of a fragment occurs. This is most commonly seen in fractures of the scaphoid and neck of the femur where the proximal fragment or femoral head is avascular.

5. **Infection.** This causes fibrosis and interference with the circulation and may also result in faulty immobilization.

Fig. 555.—Nonunion and malposition of tibia

ments by operative means leads to nonunion. In fractures of long bones a part of the shaft may be missing (e.g., gunshot wounds). Such gap fractures fail to unite unless bone is grafted or unless the ends are opposed.

2. **Inadequate immobilization.** Constant movement at the fracture line creates the conditions required for a false joint or pseudarthrosis. Practically all fractures will unite if properly reduced and immobilized for a sufficiently long period.

6. **Absence of functional use of the part.** Stress and strain both stimulate union if achieved without shearing at the fracture line.

7. **Old age, invalidism, poor nutritional state.**

8. **Pathologic conditions of bone** when the fracture occurs through a malignant growth of primary or secondary nature.

Degrees of Nonunion.—

1. **Absolute nonunion**—a gap exists, e.g., separated fracture of patella.

2. Fibrous union—ends are sclerosed and dense fibrous tissue exists between the fragments.

3. Pseudarthrosis—a false joint has developed.

Treatment.—Delayed union and nonunion are best prevented by correctly applying the

a bone graft to open up fresh vascular channels in each fragment, and at the same time afford internal fixation, is the procedure of choice. Drilling of the sclerosed ends after exposure or freshening the bone ends and application of a metallic plate may be used in certain cases.

Fig 556—Pseudarthrosis of the humerus

proper treatment to the fresh fracture. When delayed union is diagnosed the first consideration is given to the probable causes which have been enumerated, and, if possible, such are corrected. Often proper immobilization of the fracture associated with graduated function will accelerate the healing process.

When sclerosis of the bone ends has occurred and nonunion is established, the use of

MAL UNION

When fractured fragments have united in an overlapped, angulated, or displaced position, the fracture is said to be *malunited*.

Causes —

1. Failure of adequate reduction
2. Failure of adequate immobilization.
3. Displacing forces of muscular pull, faulty traction, or faulty splinting.

Treatment.—If sufficiently severe to interfere with adequate function or for cosmetic reasons, the area may be exposed, the bone refractured, and the corrected position obtained.

Immobilization is then secured by internal or external fixation

Fig 557.—Sliding bone graft of tibia. The bone graft is cut from the anteromedial surface of the tibia across the fracture line. The portion of the graft below the fracture line is removed, and the remaining bone graft is driven down across the fracture line and appropriately fixed with screws, two above and two below. The residual portion of the graft is placed in the defect in the upper tibia.

MYOSITIS OSSIFICANS

When muscle, ligament, or periosteum is avulsed from its bony attachment, a hematoma develops. In this matrix osteoblasts proliferate and produce bone. Irritation by stress or strain during the early stages increases this bone formation. The most common site for this

development is around the brachialis anticus insertion after dislocation of the elbow.

Treatment.—When the presence of the calcified shadow is seen on x-rays after a joint injury, attention should be directed to prevent any passive stretching of the area. No operative procedures should be considered until the range of movement has become stationary and the x-rays show a dense shadow. If such constitutes a bony block, excision should be considered.

Fig 558.—Myositis ossificans

ASEPTIC NECROSIS

Following a fracture or dislocation, the blood supply to a fragment or area of bone may be less than the nutritional requirements. When such occurs the part undergoes aseptic necrosis. If in a position to be revascularized, the granulations grow into it and the bone is replaced by creeping substitution (Pendergast).

Union of fractures where one fragment is avascular is greatly delayed. This is seen in cases of fractures of the scaphoid with a small proximal fragment, in fractures of the femoral neck with death of the head, and in segmental fractures of long bones such as the tibia.

Joints

H. Fred Moseley, D.M.

The function of joints is to permit movement of the bones that make up the articulation. This movement occurs between the smooth articular cartilages that cover the bone ends. Secretion of lubricating fluid by the synovial membrane is controlled by functional requirements. The range of motion is determined by the shape of the articulating surfaces, the capsular and ligamentous attachments, and the musculature related to the bones concerned. Injury and disease have as their chief complication interference with this gliding mechanism and consequent joint stiffness.

INJURIES

Penetrating Wounds

The superficial joints of the hand, foot, knee, or elbow may be contaminated by puncture wounds or opened by laceration. Foreign bodies such as parts of needles, pins, nails, glass, projectiles, clothes, wood, and dirt may all form part of the injuring force.

Treatment.—The probability of infection indicates the serious nature of these lesions. At the earliest moment, the wound tract should be excised under appropriate anesthesia. Foreign bodies are removed and the joint irrigated with saline. Penicillin in aqueous solution is instilled into the joint cavity. The synovial membrane is closed without drainage. If all contamination has been removed within 6-12 hours of the accident, the superficial

wound may be closed, otherwise it is arranged for secondary suture on the 5th day. A pressure bandage is applied. The limb is splinted in a bivalved cast. Systemic penicillin is given until the possibility of infection has passed.

If the patient is seen later and the joint presents an effusion with local and general signs of infection, aspiration of the fluid and daily instillation of 300,000 units of aqueous penicillin are performed. The bacteriologist determines the causative organisms and the chemotherapeutic or antibiotic agent required. For penicillin-sensitive organisms, penicillin can be injected locally into the joint together with intramuscular administration. Joints which in former years were destroyed by suppurative arthritis can thus be salvaged.

Ligaments

These are the capsular thickenings that prevent abnormal displacements of the bones. The ligament is blended with the periosteum and through this is attached to the bone by dense fibers penetrating along Volkmann's canals. Muscular balance prevents excessive tension on ligaments, and rupture does not occur unless these muscles are caught off balance or the force involved is greater than the protecting power of the muscles concerned.

The usual injury is a sprain which may be defined as a rupture of the fibers near the bony attachment. Sprains may be incomplete,

involving only a few fibers, or complete, when all the fibers are ruptured. Sometimes the ligament avulses the piece of bone to which it is attached, giving a sprain fracture.

Treatment.—Incomplete sprains do not cause joint instability, and treatment is palliative. Adhesive strapping arranged to minimize tension on the affected fibers suffices. Cold applications for 6-12 hours, followed by heat, massage, or even Novocain infiltrations, can be used to diminish pain.

Complete sprains and sprain fractures, as they permit joint instability, deserve as serious consideration as fractures and often produce more prolonged disability.

Complete sprains of the external collateral ligament of the ankle should be treated in a walking cast for 6-8 weeks. Sprains of the internal collateral ligament of the knee are usually incomplete, and strapping support suffices. When the ligament is completely torn in association with dislocation or valgus fracture dislocations, operative suture is probably best. Sprain fractures, with displacement of the medial malleolus, require open operative suture. Severe sprains of the wrist must always be differentiated from the fractured navicular by careful radiologic studies.

Subluxations and Dislocations

When ligaments and capsule are sufficiently torn to permit joint instability, the articulating surfaces may displace partially or completely on each other. Partial displacements are usually self-reducing and are called subluxations. When complete separation of the surfaces occurs, the bones are locked in the displaced position by muscular spasm, and these complete persistent displacements are called dislocations.

If the initial treatment does not secure capsular and ligamentous healing, the instability persists and the joint is subject to recurrent subluxations or dislocations. The shoulder most frequently presents this clinical syndrome.

Occasionally dislocations are compound in nature or associated with a fracture. Damage to nerve or blood vessel may occur at the initial injury or result from forcible manipu-

lative procedures. Pathologic dislocations occur when tense effusion and inflammation destroy the ligaments and joint stability, thus permitting gravity and muscle imbalance to displace the component bones.

Treatment of Acute Dislocations.—Early reduction under anesthesia affording complete relaxation of muscular spasm is indicated. The part should be protected until healing of the ligaments is secured. Re-education of joint movements and musculature is then essential.

Internal Derangements

Injury and disease may result in the presence of tissue which intrudes between the joint ends. Such tissue may be unorganized, as is found in chronic infective synovitis with formation of fibrin concretions called melon or rice seed bodies, or may be organized tissues of fibrocartilage, articular cartilage, or bone.

When completely detached, these fragments are called loose bodies and give rise to recurrent effusions, joint locking, and instability. By far the most common internal derangements occur in the knee from rupture of the semilunar cartilages.

Traumatic Synovitis and Hemarthrosis

Joints which are subjected to a direct blow or a severe sprain become painful and filled with an excess of thin synovial fluid. This condition is called traumatic synovitis and the collection of fluid a joint effusion. If the ligaments are torn or a fracture into the joint is present, hemorrhage may fill the joint, giving an hemarthrosis. Unless severe tissue damage is present, the blood remains fluid. Both these conditions may follow joint operations.

Treatment consists in aspiration of tense effusions and application of pressure dressings. In the knee and ankle, protection from weight-bearing is advisable, but joint and muscle exercises assist absorption and accelerate recovery.

Traumatic Arthritis

When injury to the bones or articular cartilage leaves a residual mechanical derangement

JOINTS

of a joint or when capsular and ligamentous tears give permanent instability to the articulation, the wear and tear processes are accentuated and gradual destruction of the joint mechanism ensues. This destructive process is called *traumatic arthritis*.

Traumatic arthritis is most commonly seen in the weight-bearing joints but especially occurs in the closely fitting joints such as the ankle and elbow. Aseptic necrosis of articular fragments such as the femoral head and proximal half of the scaphoid leads to this deterioration if protection from stress and strain is not secured during the revascularization of the ischemic fragments.

Treatment.—Traumatic arthritis is minimized by accurate reduction of fractures involving the articular surfaces together with the removal of loose fragments of bone or cartilage from the joint cavity. Avoidance of function by splinting is required in simple injuries of joints for a period of 2-3 weeks, but in cases with aseptic necrosis the time factor will be governed by radiologic evidence of revascularization.

INFECTIONS

Bacteria may be carried to joints by the blood stream, introduced directly by wounds, or invade from adjacent bone or soft tissue infections.

Acute Pyogenic Arthritis

The bacteria most commonly found are streptococci, staphylococci, pneumococci, and occasionally *Salmonella typhi*. These reach the synovial membrane by the blood stream and initiate an inflammatory reaction. A seropurulent exudate develops which gradually increases in quantity, distending the joint cavity. The limb takes up the position of comfort, i.e., flexed 20 degrees. The tension and inflammatory involvement of sensitive tissue result in great pain which is evoked by the slightest movement. Intensive muscle spasm is Nature's protective response.

Clinical Picture.—The patient presents the general reaction to infection with raised temperature, pulse rate, and leukocytosis. The degree varies with the severity of infection.

Locally the joint is warm, swollen, and tender. All movements are resisted by the patient.

Diagnosis.—History of infection elsewhere, such as otitis media, tonsillitis, skin infections, or pneumonia, suggests the site of origin and type of bacteria involved. Aspiration of the joint with microscopic examination and culture is essential.

Treatment.—Bed rest and general supportive measures are indicated. Aspiration of the joint fluid and instillation of 1 million units of penicillin should be performed daily until the correct antibiotic has been ascertained. Intramuscular penicillin is also given. Systemic and local antibiotic therapy should be continued until resolution occurs. The limb is splinted in the position of greatest comfort.

When the infection has been overcome, gradual restoration of function can be obtained with physiotherapy.

Gonorrheal Arthritis

Infection of joints and synovial sheaths of tendons and bursae occasionally occurs and then usually in the 3rd week after genital tract infection in the adult. Spread is by the blood stream. Such involvement is infrequent since the advent of penicillin.

The clinical picture differs from that caused by streptococci and staphylococci in the lesser degree of toxemia and systemic reaction. Locally the joint signs are similar. The process may involve several joints.

The arthritis is rapidly cleared by penicillin which has replaced previous therapies such as treatment by hyperpyrexia.

Chronic forms of neisserian involvement of joints are associated with chronic synovitis giving recurrent effusions and with a form of articular rheumatism.

Tuberculous Arthritis

Arthritis caused by the tubercle bacillus is one of the most serious and disabling types of joint disease. Before the pasteurization of milk and herd testing, the bovine bacillus was a frequent invader of joint tissues.

The bacilli reach the region by the blood stream from a primary focus in lymph gland

Fig 559 —Tuberculous wrist

Top, clinical appearance, center, x-ray appearance, bottom, after bone graft

or pulmonary tissue. The initial lesion may be in the juxta-articular bone with secondary involvement of the synovia or it may start in the lining membrane. An indolent, slowly progressing granulomatous thickening of the membrane occurs. The cartilage is eroded and sequestered by the carious process, and the ligaments are destroyed. Muscle spasm develops early and joint stiffness presents on clinical examination.

Diagnosis.—The patient may present the general picture of tuberculosis with loss of weight, afternoon elevation of temperature, and night sweats. If seen early, the joint signs,

shows marked osteoporosis and loss of joint spacing.

Treatment.—

General.—The joint process is only part of the systemic disease and the general treatment of tuberculosis is essential. Long periods of observation in tuberculosis centers are necessary, with supportive therapy and training in the way of life required. Streptomycin has been found useful in joint tuberculosis and is given in a dosage of 1 Gm twice weekly associated with a daily dosage of 12-20 Gm. of para-aminosalicylic acid or one of the isonicotinic acid derivatives such as isoniazid

Fig 360—X-rays of tuberculous hip—early and late stages. Note the osteoporosis involving the acetabulum, head, and neck of the femur with loss of the joint space in the early stage. In the late stage the joint has been destroyed and bony ankylosis has occurred. The bone healing is indicated by the increased density of the bone as shown by x ray.

such as a limp when tired if a lower limb joint is involved, are minimal. X-rays at this stage may be negative. Tuberculin tests are positive. There is a relative lymphocytosis and raised sedimentation rate.

With progress of the disease, the joint becomes swollen, and its movements are restricted. Local heat is not obvious. In the knee the thickened synovial membrane and enlarged joint contrasted with the wasted thigh and calf give the classic appearance to which the term "white swelling" is applied.

Aspiration of the joint with guinea pig inoculation is necessary for diagnostic purposes. In doubtful cases biopsy is indicated. X-ray examination in the fully developed case

A course of treatment covers, on the average, a period of 60-90 days. When secondary sinuses are present, local application is utilized as well. Closure of sinuses can now be expected with this treatment.

Local.—The principle of treatment for joint tuberculosis is rest. In the young, conservative measures employing casts and braces are used. In the adult, resection of the joint and arthrodesis are indicated during a period when the bodily reaction to the disease is favorable as indicated by normal temperature, pulse, and gain in body weight.

Syphilitic Arthritis

The incidence of syphilitic disease of joints has been greatly diminished by active public

health programs and free medical treatment. Cases, therefore, are rarely seen, but clinical types must be kept in mind for differential diagnosis.

The *early stage* is sometimes associated with arthralgia involving several joints, especially the knee, and may be accompanied by a chronic form of joint effusion. General anti-syphilitic treatment affords relief.

bilateral and symmetrical and lacks the general systemic toxemia seen in tuberculosis. Biopsy of the synovial membrane may be required.

Gummatous synovitis is also seen in children 8-14 years of age who show the stigmas of congenital syphilis, such as interstitial keratitis, saddle nose, and Hutchinson's teeth. The process is usually bilateral and involves the knees in a painless effusion.

Fig 561—X rays of Charcot's knee. Note the irregular calcification of the soft tissues in the lateral view. A marked effusion must be present to displace the patella so markedly. In the antero-posterior view the joint laxity is indicated by the loss of accurate apposition of the femoral condyles and tibial plateau.

The *late stage* presents the gummatous process in the tissues and this may cause an infiltration of the synovial membrane, giving an indolent form of peri-arthritis.

Diagnosis.—This is made with recognition of the systemic disease. The Wassermann reaction is positive. The process must be differentiated from tuberculous synovitis. It will be noted that the syphilitic process tends to be

The name *Clutton's joints* is given to this condition.

Painless nodules occur quite frequently around joints. These juxta-articular nodes vary from pea to walnut size.

Treatment.—This consists of general anti-syphilitic measures. Relief from weight-bearing and splinting limits excessive function.

Charcot's Joints

Patients with tabes dorsalis and syringomyelia may present a rapid, painless destruction of one or more joints. In both of these diseases the spinothalamic tracts are destroyed, with loss of pain sensation. This is regarded as the causative factor in the joint changes since injuries are not associated with pain, and protective muscular action is absent. Syphilitic arteritis in the vessels supplying the joint probably also predisposes to the degenerative changes.

The joints most frequently involved are the knee, hip, ankle, shoulder, and spine.

Clinical Picture.—This is made on the above findings in addition to the presence of the neurologic signs of tabes or syringomyelia.

VARIOUS TYPES OF ARTHRITIS

Degenerative or Osteoarthritis

This is the most common form of joint disease and is the result of the wear and tear processes of daily life. The inherited constitution and vitality of the joint tissues are determining factors in its occurrence since the process runs in families. Injury, excessive weight, and chronic postural strain all play a part. It is characteristically seen in the patient over 50 years of age and most commonly involves the weight-bearing joints, i.e., knee, hip, and spine.

Pathology.—The soft tissues of the joint such as the ligaments and synovial membranes show the most marked changes. The ligamentous attachments are frayed and the synovial membrane thickened and hypertrophied into villous fringes. The cartilage over the weight-bearing or pressure points becomes fibrillated and gradually sequesters into the joint, giving rise to loose bodies and recurrent effusion. Gradual deterioration of the whole joint then ensues.

Diagnosis.—Clinically the joint presents the signs of an irritative process. The movements are restricted in all directions and pain is elicited on manipulation. The knee takes up a position of flexion, while the hip becomes flexed and adducted with some external rotation. X-rays show typical *lipping* and possibly

loss of joint spacing. Examination of the hands may show the characteristic Heberden's nodes.

Treatment.—In the early stages, protection from excessive function, with diet to cause loss of weight in the obese, will help. Salicylates and physiotherapy relieve. Intra-articular injections of 1-2 ml. hydrocortisone acetate have been found beneficial, especially for the knee. When loose bodies form, arthrotomy with removal of debris sometimes gives excellent results. In late stages, orthopedic procedures such as arthroplasty or arthrodesis may be required.

Gouty Arthritis

Uric acid deposition in patients with gout may occur in any articulation. The great toe joint is the site of election. The knee, hip, lumbar spine, and elbow (olecranon bursitis) all may present acute or chronic involvement.

Treatment.—Colchicine 0.5 mg. hourly till diarrhea occurs is most effective in the *acute attack*. Intravenous injection of 3 mg. colchicine gives dramatic relief. Butazolidin 800-1,200 mg. daily is also valuable. Cold applications and protection from pressure or tension are fundamental in the local therapy. The patient with a chronic case must be advised to moderate his diet which should be low in fat and red meat. Alcoholic beverages are prohibited. Salicylates and a maintenance dosage of colchicine, 5 mg. b.i.d., are beneficial in preventing further attacks. Benemid 1 Gm. t.i.d. is also useful in increasing the excretion of uric acid. Moderation in food, drink, work, exercise, and sexual activities will be found the best way of life.

Rheumatoid Arthritis

These cases are seen on the surgical wards only in the late stages, presenting the deformities of chronic polyarticular disease.

The characteristic fusiform swelling of the proximal phalangeal joints, the flexed swollen knees, flexed and adducted hips, and plantar flexed feet from ankle involvement are usually present.

Treatment of a surgical nature is directed to orthopedic procedures such as correction of

Fig 564—X-rays of degenerative arthritis of knee with loose bodies, patella and loose bodies removed from knee

Fig. 365 —A, Advanced gouty arthritis of great toe joint with sinus formation
B, Similar changes involving the joints of the hands

deformity by manipulative measures and establishment of the capacity for ambulation by reconstructive and arthrodesing operation on the weight-bearing joints involved. The use of gold, cortisone, and ACTH, together with active physiotherapy, has greatly diminished the frequency of serious deformities.

Chapter 38

Bursae

H. Fred Moseley, D.M.

The word *bursa* is derived from the Latin *bursarius* and signifies a sac. Such bursae or sacs are formed of a fibrous outer membrane and are lined by a layer of mesothelial cells which secrete the lubricating fluid corresponding to the synovial fluid in joints.

Bursae are found in constant sites in the human body and function to diminish friction and obviate pressure where one plane of soft tissue, such as skin or tendon, glides over another plane which usually presents a prominence of bone or tendon.

The *constant bursae* are those shown in Fig. 566, but bursae may develop as the result of a deformity that produces a prominence over which the soft tissues must move or as the result of an occupation that subjects a certain area to repeated pressure and movement of soft tissue over the underlying skeletal parts. Such occasional sacs are called *adventitious bursae*. Some bursae communicate with joints, such as the semimembranosus bursa behind the knee. This has been described as a posterior herniation of the synovial membrane. Other bursae may communicate with joints as the result of attritional changes in the intervening tendon or capsule. The best examples of such lesions are found in the subacromial, iliopsoas, and prepatellar bursae.

Chronic bursal disease often necessitates surgical removal. This is followed by reformation from the residual bursal and adjacent areolar tissues in response to functional activity of the parts.

TRAUMATIC BURSTITIS

Trauma affects the bursal mechanism in the same variety of ways and with the reactions corresponding to those described for joints.

The superficial bursae such as the olecranon and prepatellar bursae may be injured by a penetrating wound. Such open or compound injuries will be diagnosed by the presence of the wound, which on examination leads to the lumen of the bursa and shows the discharge of mucinous fluid.

Treatment includes the careful excision of the wound edges and primary suture if seen within the period before infection has supervened on the contamination. The part should be locally splinted to secure rest and penicillin given to prevent the development of infection.

If the patient is seen after the infective process has developed in the wound, the bursal wall will be thickened and a seropurulent discharge will be present.

Treatment at first should be conservative with local rest by splinting of the part. The discharge should be studied as to its bacterial content and antibiotic sensitivity. Penicillin is best given immediately and changed to the appropriate antibiotic if the organism is not penicillin-sensitive. Some cases will require excision of the chronically infected bursa when the active infection has been controlled.

Trauma may also set up an acute traumatic bursitis as a result of a single contusion or from repeated unusual pressure and friction.

A direct fall on the point of the elbow or knee may initiate the process in the olecranon or prepatellar bursa. Working in the supine position under a car or aeroplane with pressure on the elbows and scrubbing floors on the knees are common causes.

The irritated bursa fills with serous fluid containing more or less blood, depending on the severity of the injury. In the contusion injuries, fissured fractures of the underlying bone or rupture of the tendon attachment or periosteum may be present

villous processes of the mesothelial lining develops. There is an excess of fluid present which is more serous in character than normal. The bursa tends to fill up and becomes painful on overuse. In time, loose bodies of a fibrinous or even calcified nature may form, and pressure on the area may be extremely painful. The bursa involved is subject to recurrent attacks of pain and the muscles in the area may exhibit painful protective spasm.

The treatment of the chronically thickened bursa presenting recurrent attacks of pain and

Fig 566—Bursae of the upper and lower limbs

Treatment consists of rest to the part with application of cooling lotions for the first 8-12 hours to diminish the traumatic inflammatory process, followed by heat and massage and gradual resumption of function to accelerate the absorption of the inflammatory products. If the bursa is tensely swollen, aspiration of the fluid followed by a pressure dressing to diminish reformation accelerates the recovery and affords relief of pain.

Although an acute trauma frequently produces bursitis, chronic repeated trauma of lesser degrees is the most common factor. The changes in the bursal wall are more gradual, and in time a thickened fibrous wall with

swelling is excised. Conservative measures such as rest and protection from injury are justifiable in the early stages. Aspiration of the fluid is usually followed by recurrence. Instillation of 1 ml. (50 mg) hydrocortisone acetate is sometimes of value.

INFECTIVE BURSTITIS

Pyogenic infections of bursae may be primary and result from direct introduction by penetrating wounds or may be metastatic due to hematogenous spread in cases of septicemia. Antibiotic treatment is usually adequate, and drainage by aspiration is rarely required.

Gonococcal infection occurs secondarily to a genital tract infection and is controlled by penicillin.

Tuberculosis may develop in bursae, usually by spread from adjacent bone or joint lesions. The trochanteric bursa is a typical site for such a tuberculous lesion, and radiologic examination will reveal changes in the underlying bone once the disease is well established.

Syphilitic bursitis is much less commonly seen today because of the early efficient treatment of the systemic disease. It is characteristic of the tertiary gummatous stage, and the bursae most frequently involved are the prepatellar bursae. The process is typically bilateral and symmetric.

The diagnosis is suggested by the presence of bilateral thickened bursae which are typically painless and have developed without adequate traumatic cause. The serologic examination and clinical history will establish the presence of syphilis.

Treatment consists of the systemic treatment of syphilis.

METABOLIC BURSITIS

In this group of cases may be included, for descriptive purposes, bursitis due to deposits of uric acid and its derivatives and to deposits of the phosphate and carbonate of calcium.

Systemic gout with the recurrent precipitation of uric acid around joints leads to attacks of acute pain which are most frequent in relation to the great toe joint and related bursa. Sudden pain in relation to the olecranon bursa with diffuse swelling without apparent cause is sometimes due to gout.

Deposits of calcium phosphate and carbonate are most typically seen in the rotator cuff of the shoulder with secondary involvement of the subacromial (subdeltoid) bursa, although as in gout any joint or bursal mechanism may be involved.

In the cases of lesser severity of involvement by deposits of uric acid and of the phosphate and carbonate of calcium, we have the explanation for many syndromes loosely diagnosed as rheumatism, arthritis, neuralgia, and neuritis.

BURSAE OF THE UPPER LIMB

Three constant bursal mechanisms of the upper limb commonly present clinical syndromes. In order of frequency, these are subacromial (subdeltoid), olecranon, radiohumeral.

Subacromial (Subdeltoid) Bursitis

Involvement of this bursa is the most common cause of shoulder pain, and this is the "bursitis" so frequently discussed in the lay press.

Fig 367—A calcified deposit which has ruptured into the subacromial bursa.

Knowledge of this entity was disseminated by Codman, who demonstrated that the bursa is secondarily involved by inflammatory processes due to trauma, degeneration, and calcified deposits in the subjacent rotator cuff. The bursa functions as a secondary joint mechanism between the humeral head and the coracoacromial arch, and this gliding mechanism is necessary for the movements of rotation and elevation of the arm above the horizontal plane.

Contusions of the area from falls on the upper limb, degenerative changes, and calcified deposits in the underlying cuff produce irritation of the sensitive bursal lining. Depending on the severity of the inflammation

are the intensity of pain and limitation of function

In the typical case due to calcium deposition, the patient gives a history of recurrent rheumatic pain on change of weather or overuse. The acute attack develops suddenly with inability to raise the arm, and sleeping on the affected side is impossible due to the severe pain. X-ray examination will indicate the presence or absence of calcium deposits

Treatment.—Conservative measures include support in a sling and rest to the part. Cooling applications or an ice bag affords more relief in the acute phase than heat. Analgesics are

pulley exercises. X-ray therapy has many advocates

In the chronic cases with and without the x-ray presence of calcium deposits, the use of diathermy, exercises, and the protection by wool garments in cold weather are advocated

Olecranon Bursitis

Acute, recurrent, and chronic forms are seen and are related to varying occupations subjecting the elbow area to repeated friction, pressure, or contusion. Miners, students, and mechanics are especially afflicted. The acute

Fig. 568—Chronic olecranon bursitis

required for pain. If not contraindicated by a history of peptic ulcer, ulcerative colitis, severe diabetes, tuberculosis, or psychotic states, Meticorten 10 mg. q.i.d. for 4 days, followed by 5 mg. q.i.d. for several days, has been found most efficacious when combined with local therapy. Needling with local anesthetic infiltration and injection of hydrocortisone (compound F) afford benefit in some cases.

If x-rays show a large deposit of calcium, surgical excision during the acute phase is best. Proper treatment for small deposits is a course of physiotherapy, including heat and

forms subside with rest, but the recurrent and chronic types frequently necessitate excision of the bursa

Radiohumeral Bursitis

This bursa is situated between the common extensor origin and the supinator brevis. Irritation of this mechanism by excessive pronation and supination is one cause of "tennis elbow." Rest, heat, and salicylates usually afford relief. Infiltration with local anesthetic followed by injection of 1 ml. of hydrocortisone (compound F) sometimes produces dramatic results.

BURSAE OF THE LOWER LIMB

The constant bursae of the lower limb are more frequently subjected to trauma than those of the upper limb. The bursae commonly involved are ischial, trochanteric, semimembranosus, metatarsophalangeal, psoas, prepatellar, calcaneal.

Ischial Bursitis (Weaver's Bottom)

A large bursa exists between the gluteus maximus and the ischial tuberosity and hamstrings origin. Constant friction and pressure from occupations involving the seated position for prolonged periods may initiate a bursitis. The chronically distended bursa may produce a swelling of considerable size. Treatment is excision.

Psoas Bursitis

A bursa exists in relation to the anterior capsule of the hip joint and communicates with the joint in certain cases of degenerative and tuberculous arthritis. Chronic enlargement of this bursa is thus a lesion for differential diagnosis in swellings of the groin.

Trochanteric Bursitis

Several bursae exist in relation to the great trochanter of the femur. The large bursa deep to the tendon of the gluteus maximus may be acutely involved by calcified deposits in this area. Tuberculosis of the adjacent bone may cause a chronic process in this bursa.

Prepatellar Bursitis

This type was frequently seen in the domestics and cleaners of a previous generation. The acute form was presented by the uninitiated worker who attempted to scrub a large area from a fixed position. Today, with modern apparatus, "housemaid's knee" is seldom seen. Bilateral disease of chronic nature with grossly thickened bursae should suggest syphilitic involvement. Serologic examination, if positive, will confirm the diagnosis, and systemic treatment is curative.

The treatment of the chronically inflamed bursa is excision. The acutely inflamed bursa will subside with rest.

Semimembranosus Bursitis

This form of bursitis may be the cause of leg pain with stiffness in the movements of the knee. Examination of the popliteal space will reveal an oval tense swelling which disappears on flexing and becomes prominent on extension of the knee. It is typically seen in young boys 10-15 years of age, and if causing sufficient symptoms, it is best excised.

Fig. 369—Arthrogram, using Diodrast, showing communication of popliteal cyst with knee joint.

In older patients with arthritis or an internal derangement of the knee such as a posterior meniscus tear or chondromalacia of the patella, the bursa, if in communication with the joint cavity, will act as a blow valve and distend when the joint presents an effusion. Such distended bursae should not be excised. Treatment should be directed to the joint disease.

Excision of the grossly enlarged bursa causing pressure in the calf is indicated in

cases of extension of the disease process from rheumatoid arthritis involving the knee.

Calcaneal Bursitis

Bursitis may involve the bursa between the Achilles tendon and the bone or the subcutaneous bursa over the posterior prominence. Both types are due to ill-fitting shoes, and correction of this problem and protection from further injury suffice.

Metatarsophalangeal Bursitis

Inflammation of the bursa over the great (bunion) or small toe joint (bunionette) is a common complaint from ill-fitting shoes. Because of style and fashion, female patients predominate. Most disorders are chronic. Treatment must be devoted to correction of the chronically deformed structures by orthopedic procedures. Properly fitted shoes must be prescribed.

Fractures and Other Disorders of the Upper Extremity

Fractures and Other Disorders

H Fred Moseley, DM

CLAVICLE

The clavicle is so called from its resemblance to the clavicle of the musical score. It is highly developed in man but may be congenitally absent, i.e., cleidocranial dysostosis. This bone is absent in certain running and jumping animals, e.g., the horse.

Functional Anatomy.—The clavicle functions as:

- 1 A strut to keep the glenohumeral joint clear of the trunk, thus increasing the range of the hand as the effector organ of grasp
- 2 A rigid attachment for powerful muscles
- 3 The only bony connection of the upper limb and trunk
- 4 A protection to the vital structures in the cervicobrachial and thoracobrachial outlets
- 5 A cosmetic factor at the base of the neck

Incidence.—Fractures of this bone are four times more common in the male than in the female. Sites of fracture. body—outer end—inner end

Mechanism—The usual cause is the transmission of force indirectly from a fall on the outstretched hand, elbow, or point of the shoulder. Fractures occasionally result from direct violence.

Fractures of the Body

The body is the area most frequently fractured. This portion marks the junction of the curvatures and has little protection from muscular or ligamentous attachments. Greenstick fractures are common in young children.

In complete fractures, the sternomastoid draws the inner fragment upward, whereas the weight of the limb causes the outer fragment to be displaced downward, forward, and medially.

Diagnosis.—This is made on the history, the point of local tenderness or deformity, the localization of pain and crepitus to the clavicle on movements of the arm, and the positive x-ray findings.

Principles of Treatment.—These are as follows:

1. To brace the whole shoulder girdle so as to carry the outer fragment upward, outward, and backward
- 2 To depress the inner fragment
3. To maintain reduction
4. To continue active function of the hand, elbow, and shoulder during immobilization of the fracture
5. To check progress by x-ray

Fig 570—Anatomy of the clavicle

Fig 571—Fracture of clavicle showing typical deformity. The shoulder girdle falls inward and downward, diminishing the prominence of the shoulder. Note how easily injury to the neurovascular bundle could occur.

Discussion of Present-Day Methods.—Unless some contraindication exists, most surgeons are content to use conservative methods and try to achieve good results by understanding the principles of reduction and using the following for support.

1. The three-handkerchief or figure-of-eight bandage
2. The figure-of-eight plaster cast

3. Adhesive strapping
4. Bandage to shoulder cross
5. Various commercial splints of light metal

The three-handkerchief method is the simplest to use, but it is necessary to explain to the parents of children or to the adult patient the principles involved: the necessity to hold the shoulder braced upward and back.

Fig. 572 —Fracture of the body of clavicle with typical displacement

Fig. 573 —Three-handkerchief bandage applied for fractured clavicle.

ward and the daily adjusting and padding of the bandages. Meticulous reduction and supervision are required in the young lady where the cosmetic result is important. Three to four weeks' immobilization is usually adequate.

Open operation is rarely required. If malunion must be prevented, the introduction of an intramedullary wire (Murray) is best. This must not be lightly undertaken. Exposure of the fracture site with insertion of the wire under direct vision will prevent penetration into important structures in this area.

Fractures of the Outer End

Such fractures are protected from marked displacement by muscular and ligamentous attachments. Splinting is often unnecessary and may be minimal. When the fracture involves the acromioclavicular joint, resection of this portion eventually may be indicated.

Fractures of the Inner End

Fractures of the inner end are protected from marked displacement by the muscular and ligamentous attachments. The routine methods of treating fractures of the body are therefore not usually necessary for fractures of the inner or outer end. A sling is sufficient.

Complications of Clavicular Fractures

Nonunion is uncommon except after infection or unsuccessful operative intervention. *Treatment* consists of freshening the bone ends and employing intramedullary fixation supplemented by onlay or cancellous bone grafts.

Stiffness of the shoulder is the most common complication in patients over 40 years. It is sometimes due to a concomitant injury to the shoulder joint but more commonly results from immobilization of this joint during the therapy and is best prevented by keeping the shoulder in use throughout. *Injury to the subclavian vessels, dome of the pleura, or brachial plexus* occasionally occurs.

CLAVICULAR ARTICULATIONS

Acromioclavicular Joint

The possibility of injuries of this joint is often overlooked.

Functional Anatomy.—The joint depends for its strength on the coracoclavicular ligaments as well as the capsular ligaments strengthened superiorly by the aponeurotic attachments of the deltoid and trapezius muscles. An intra-articular meniscus is present in 30-40% of cases. The clavicle may have an overriding articular facet with a loose joint arrangement, or the clavicular facet may be vertical with a closely knit mechanism. The joint permits a small amount of movement in all directions, functioning in the range above 120 degrees and especially in circumduction above 90 degrees abduction.

Mechanism.—Minor sprains and subluxation may be produced by forces transmitted directly or indirectly. Complete dislocations occur when the patient falls on the point of the shoulder. The whole shoulder girdle is forcibly depressed and the clavicle is arrested by the first rib. Continuation of the force causes rupture of the capsule and aponeurosis on the superior aspect followed successively by rupture of the trapezoid and conoid ligaments.

Diagnosis.—There is history of injury followed by pain over the superior aspect of the joint. In sprains and subluxations, forcible adduction of the arm across the chest will accentuate the pain, which can be localized by palpation to the posterosuperior aspect of the joint. In doubtful cases, repeated circumduction of the arm above the horizontal plane, as in throwing a ball, will assist in localizing the pain and tenderness to this joint.

In dislocations the prominence of the outer end of the clavicle is obvious. X-ray examination confirms the displacement and is best done with the patient standing with a 25 pound weight in each hand. Rupture of the coracoclavicular ligaments can thus be readily diagnosed by increase in the coracoclavicular spacing.

Treatment.—For patients without rupture of the coracoclavicular ligaments, no special treatment is required. It is probable that, if symptoms persist for any length of time, the lesion is a derangement of the intra articular meniscus.

In those with complete dislocation, conservative treatment with the shoulder girdle elevated

Fig 574—Acromioclavicular dislocation

Fig 575—Complete dislocation of acromioclavicular joint with increased coracoclavicular spacing indicating rupture of conoid and trapezoid ligaments.

and downward pressure applied over the outer end of the clavicle for 6 weeks will result in good function in the majority of cases. This position can be secured and maintained by adhesive strapping and sling or in a plaster spica. Some deformity usually persists.

In patients who are left with a painful joint after minor injuries or with dislocation after conservative treatment and in some acute dislocations, resection of the outer inch of the clavicle with repair of the conoid and trapezoid ligaments by suture of the clavicle to the coracoid process with fascia or silk gives rapid and excellent results. This is recommended in preference to fascial or metallic repair of the joint.

Sternoclavicular Joint

The sternoclavicular is an exceptionally strong joint and is the pivot for movements of the shoulder girdle, i.e., elevation, depression, protrusion, retraction, and circumduction. It is less frequently injured than the acromioclavicular joint. It constitutes the articulation between the upper limb and the trunk and is involved in sprains, acute and recurrent subluxations, and dislocations. Anterior dislocations usually occur. Posterior dislocations are less common but more serious because of possible pressure on, or damage to, the trachea, esophagus, and great vessels.

Mechanism.—Injury to this joint results from forcible pressure of the clavicle forward and inward. The capsule is torn and forward subluxation or dislocation occurs.

Diagnosis.—The prominence of the inner end of the clavicle is readily seen. Tomograms afford useful x-ray visualization of this joint.

Treatment.—In sprains and subluxations no special treatment is required. In complete dislocation, reduction is readily effected by bracing the shoulder backward and manually pressing the sternal end into place. This reduction is difficult to maintain and requires a plaster spica for 3-4 weeks with the arm at 90 degree abduction and 45 degree forward flexion with direct pressure over the joint in a backward and downward direction. Sometimes the figure-of-eight plaster bandage suffices as for a fractured clavicle.

In some acute and some recurrent dislocations, a fascial repair (Bankart) may be carried

out or the sternal end of the clavicle may be resected, if the patient's symptoms of pain and functional derangement warrant operative treatment.

FRACTURES OF SCAPULA

Fractures of the scapula are not common but occur in the following parts:

1. Glenoid fossa
2. Neck
3. Body
4. Acromion and spine
5. Coracoid process

Glenoid Fossa

Fragmentation of the bony rim may occur in anterior or posterior dislocations, especially if recurrent.

Fig. 376—Composite diagram of type fractures of the scapula

Fractures of the fossa are sustained when the humeral head is forced strongly against it by direct violence. Lesser injuries are contusions of the articular cartilage grading into multiple fissured fractures corresponding to the central dislocation found in the hip.

Treatment.—The treatment of fractures of the rim is part of that of the dislocation. Fractures of the fossa present a variable picture and are frequently associated with injury

to the humeral head. In severe cases the problem is how to minimize the inevitable traumatic arthritis.

In the majority of cases, treatment by early movement is indicated. Where loose fragments of bone or cartilage exist in the joint or where associated ruptures of the rotator cuff are diagnosed, exploration of the joint should be carried out.

ture appears similar to that of anterior dislocation of the shoulder. The deformity readily disappears on pressing upward on the elbow, and reappears on release of pressure.

Treatment.—Cases impacted in fairly satisfactory position may be treated by early movement in the relaxed muscle position. During ambulation, the weight of the limb is taken by a sling arranged so as to elevate the arm.

Fig. 577—Fracture of the surgical neck of the scapula

Neck

The fracture line may pass to the inner or outer side of the base of the coracoid. The majority are impacted without serious displacement. When the fracture line passes to the inner side and the coracoclavicular ligaments are ruptured, the outer fragment is depressed by the weight of the arm, and the clinical pic-

An axillary pad and encircling flannel bandage afford comfortable fixation.

In those patients with instability of the fragments or where other injuries necessitate bed rest, traction in the abducted position, together with elevation of the outer fragment by a band around the upper arm and arranged with gentle traction to the head of the bed for 3-4 weeks, is best.

Body

Fractures of this part are caused by direct violence or crushing injury which also frequently injures the underlying ribs. Because of the buffering and splinting action of the muscles arising from the three fossae, displacement is uncommon.

Treatment.—Aspiration of the hematoma, which often develops, may be indicated. Otherwise treatment is by early function.

Acromion and Spine

Fractures of the acromion must be differentiated from epiphyseal separation in the young or from an ununited epiphysis by contralateral x-ray in later years.

The usual cause is direct violence, but sudden action of the condensed middle segment of the deltoid against resistance may produce the fracture. The superior periosteum and aponeurosis first tears, allowing the fragment to hinge, and, if the force carries on, this is followed by tearing of the inferior periosteum with separation of the fragment by deltoid traction. If the fragment is large, some deformity of the deltoid convexity is apparent.

Treatment.—These fractures usually heal by fibrous union. Where the fragment is depressed or separated, operative treatment with resuture is indicated to give a solid origin to the deltoid.

The same principles apply for fractures of the spine of the scapula.

Coracoid Process

Fractures of the tip are most commonly associated with anterior dislocations of the shoulder. Avulsion through the base may occur in place of rupture of the coracoclavicular ligaments in complete dislocation of the acromioclavicular joint.

Treatment in both types is part of that of the associated dislocation.

FRACTURES OF THE UPPER END OF THE HUMERUS

Fractures of the various portions of the upper end of the humerus occur as isolated

injuries or may be associated with dislocations of the shoulder.

Surgical Neck

Incidence.—Fracture of the surgical neck is a common fracture and occurs chiefly in the older age groups.

Mechanism.—Dehne classifies fractures of the surgical neck of the humerus on a mechanistic basis. Three groups are defined:

1. **Lateral Mechanism.**—In this group the patient falls with the arm abducted until the surgical neck abuts on the acromion. Either the anteroinferior capsule gives way, permitting dislocation, or fracture occurs at the surgical neck from compression and the greater tuberosity is sheared off by the superior rim of the glenoid fossa. This gives a three-fragment fracture which is most stable in adduction and is displaced by abduction.

2. **Dorsal Mechanism.**—A second manner of falling is backward, and the arm is dorsi-

Fig. 578.—Nomenclature of upper end of humerus.

Centers of ossification appear in the head, and greater and lesser tuberosities at 1, 3, and 5 years, respectively. These join together to form the superior humeral epiphysis at 6 years which fuses with the diaphysis at 20-21 years.

The *anatomic neck* is indicated by the sulcus at the periphery of articular cartilage of the humeral head. The *morphologic neck* marks the junction of the superior humeral epiphysis and the diaphysis, while the *surgical neck*, so-called because it is most commonly involved in fractures, marks the area below the tuberosities and above the insertion of the climbing muscles indicated on the shaft.

Fig 579—Fracture of surgical neck

Fig 580—Impacted adduction fracture of surgical neck of humerus due to dorsal mechanism
A, Anteroposterior view B, Axillary view

flexed to break the fall. The force of the impact is taken on the elbow and transferred in an anterior and cephalad direction along the shaft of the humerus to the head restrained by the coraco-acromial arch. A fracture of the surgical neck occurs with the axis of the shaft in posterior flexion and adduction. Such fractures are often impacted and stable and consist of two main fragments.

3. *Central Mechanism.*—The fall may be directly to the affected side with the arm in varying degrees of abduction. The impact is taken by the articular head of the humerus on the glenoid fossa. Either surface may be fractured.

Besides this classification, others classify the fractures into those with the shaft in (a) *adduction* or in (b) *abduction* in relation to the head.

Fig. 381.—Displaced surgical neck fracture before and after internal fixation. Lateral views showed anterior displacement of humeral shaft which was corrected at operation.

A and B, Before operation.

C and D, After internal fixation, using two Vitallium nails.

(From Moseley, H. F.: *Shoulder Lesions*, ed. 2, New York, 1953, Paul B. Hoeber, Inc.)

Many are impacted, and it must be remembered that the fractures of the surgical neck are extracapsular and joint stiffness is largely the result of extra-articular adhesions following immobilization.

Diagnosis.—This is made on the history of a fall together with symptoms of pain and limitation of shoulder function. Palpation demonstrates tenderness at the surgical neck, and radiologic examination gives the final proof. Detailed views in anteroposterior and superoinferior planes are required. Stereoscopic views may be indicated.

Treatment.—In all cases impacted in satisfactory position and in most cases in patients over 45 years, the treatment advocated is that of immediate movement in the relaxed muscle position. A sling or collar and cuff is used for support.

In the younger patient (20-45 years), with marked displacement, the proximal fragment being abducted and externally rotated, operative treatment with internal fixation by two nails gives excellent results. Early movement is encouraged postoperatively.

Treatment in abduction splints or in traction is required in some cases

Greater Tuberosity

Contusion Fractures

In cases of anterior dislocation of the shoulder, the greater tuberosity may suffer contusion from impingement on the anterior glenoid rim (see Fig. 585). This develops into the posterolateral notch seen in recurrent dislocations. The diagnosis is made by x-ray. Treatment is that for the dislocation.

Avulsion Fractures

These occur by contraction of the supraspinatus, infraspinatus, and teres minor, often in conjunction with anterior dislocation. When the dislocation is reduced, the fragments usually fall into position as indicated by x-ray. If this does not occur, the arm may be splinted in abduction and external rotation, or the displaced tuberosity may be sutured in its normal position.

Avulsion of Supraspinatus Facet

Occasionally, only the supraspinatus facet is avulsed. This is diagnosed by x-ray and the patient's inability to abduct the arm. If it is displaced under the acromion, reduction is necessary to remove the bony block.

Two forms of treatment are possible:

1. Resuture of the torn cuff with or without removal of the bony fragment
2. Splintage in abduction for 4 weeks

Separation of Upper Humeral Epiphysis

Incidence.—These occur in children between the ages 5-15 years.

Diagnosis.—This is made on a typical x-ray picture associated with the presence clinically of a severely injured shoulder.

Fig. 582—Diagram showing separation of upper humeral epiphysis

Treatment.—In the displaced fracture, open operation is advocated with the use of Kirschner wire fixation for 3-4 weeks, followed by its removal.

When specialist facilities are lacking, fluoroscopic reduction and immobilization in adduction and internal rotation may be employed.

Lesser Tuberosity

Fractures of this tuberosity occur in rare cases of anterior dislocations of the shoulder.

and represent an avulsion fracture caused by the subscapularis

Treatment.—After reduction of the dislocation the limb is rested in a sling for 3-4 weeks, and this is followed by gradual re-education of shoulder function.

DISLOCATIONS OF THE SHOULDER

The shoulder is the most common joint to suffer dislocation.

Functional Anatomy.—The shoulder joint is part of the shoulder girdle complex and does not function as an isolated unit. The glenohumeral joint is a ball-and-socket joint possessing great mobility. The middle segment of the deltoid and the supraspinatus act as a

team, abducting the humerus on the scapula with simultaneous descent of the head in the fossa. This is the last shoulder function evolved and is the first lost after injury or disease.

The head of the humerus, covered by the rotator cuff, revolves in relation to the coracoacromial arch with interposed subacromial bursa. This mechanism is of great clinical significance and merits the name superior humeral joint. As the humerus must externally rotate during abduction, lesions in this area restrict abduction.

In abduction and forward flexion, movements of the humerus, scapula, and clavicle occur simultaneously and rhythmically, i.e., scapulohumeral rhythm. Clinical examination should center on alterations in this rhythm rather than on localized restriction of movements of the arm.

Fig 583. Anterior dislocation of right shoulder of 7 days duration. Note vascular changes in the whole limb. There is characteristic flattening of the deltoid, and the axis of the humerus is directed toward the middle of the clavicle (From Moseley, H F. *Shoulder Lesions*, ed. 2, New York, 1933, Paul B Hoeber, Inc.)

Fig 584.—Possible sites of exit of head from glenoid fossa (From Moseley, H F. *Shoulder Lesions*, ed. 2, New York, 1933, Paul B. Hoeber, Inc.)

Classification.—Anatomic considerations determine the classification of dislocations of this joint. Superiorly, the coracoacromial arch acts as a barrier to dislocation except in the rare cases of its disruption when a superior dislocation occurs. For practical purposes all dislocations occur below a line joining its anterior and posterior pillars. Inferiorly, the long tendon of the triceps acts as a strong supporting structure to the inferior capsule in the position

of abduction in which most dislocations occur. Therefore dislocations are divided into those which occur *anterior* or *posterior* to this tendon of the triceps.

The distance to which the head will be displaced anteriorly will depend on the forces concerned, and it may be mentioned that the head has even been driven between the ribs into the chest. The earlier writers classified this distance in relation to the coracoid process as *extracoracoid*, *subcoracoid*, and *intracoracoid* or *subclavicular*.

The exact position along the anterior glenoid rim at which the head dislocates will depend on the degree of abduction at the moment. The extremes are the *directly anterior* displacement caused by a fall backward on the elbow (dorsal mechanism) and the *directly inferior* displacement caused by a fall laterally with the arm in full abduction (lateral mechanism) producing the *axillary* or *subglenoid* dislocation. In this latter group is included the *luxatio erecta* in which the patient reports with the head subluxated and the arm held in full elevation.

A Simple	{ Anterior Posterior
B Recurrent	{ Anterior Posterior
C Complicated by	{ Fracture Rupture of rotator cuff Nerve injury Vessel injury

Mechanism of Injury.—*Anteroinferior* dislocation results from a fall on the upper limb in such a way that the arm is abducted and *externally* rotated, levering the humerus against the acromion as a fulcrum out of the glenoid fossa. Sometimes dislocation occurs from a direct force from behind. These two types of fall correspond to the lateral and dorsal mechanisms discussed as the basis for surgical neck fractures.

Posterior dislocation occurs with the arm in adduction and inward rotation with a force transmitted through the humerus in an upward and backward direction.

Post-Traumatic Anatomy.—Operative and autopsy findings tend to show that the usual lesions are as follows:

- 1 Separation of the anteroinferior or posterior glenoid labrum in the respective anterior or posterior dislocations

- 2 Separation of the capsule from the inferior aspect of the neck of the humerus

- 3 Separation of the capsule and subscapularis tendon with or without the lesser tuberosity

- 4 Posterolateral and anteromedial contusion fractures of the humeral head in anterior and posterior dislocations, respectively

- 5 Increased joint capacity indicative of capsular stretching

Diagnosis.—*Anterior* dislocations are diagnosed by the history of the accident, the location of pain, loss of function of the shoulder, and loss of the rounded contour of the deltoid. Palpation reveals the absence of the head under the acromion and its forward position. The axis of the humerus runs toward the middle of the clavicle.

Radiologic examination confirms the clinical opinion and should be carried out routinely to ascertain whether an associated fracture is present.

When the shoulder has been dislocated longer than 3-4 weeks, the possibility of reduction by closed manipulation becomes doubtful and the condition may be diagnosed as a *chronic* dislocation.

Posterior dislocations are not suspected and are most frequently overlooked, especially in fat patients.

Diagnosis is made on the inability to abduct or *externally* rotate the arm which is held in internal rotation. The head may be palpated in the subspinous position where maximum tenderness is present.

Routine x-rays are often inconclusive and stereoscopic and superoinferior views are a necessity.

Manipulation under an anesthetic may be the final diagnostic point.

When the patient gives a history of several dislocations, the diagnosis, *recurrent* dislocation, is made.

Treatment

Acute Anterior Dislocation

Reduction is best carried out under the relaxation provided by general anesthesia but can be effected without this assistance.

FRACTURES OF THE UPPER EXTREMITY

Fig 585—Cross section of anterior dislocation of shoulder. Note the detachment of the glenoid labrum and subscapularis anteriorly, permitting the dislocation to occur. The fracture produced by impact of the articular head in the posterior area of the greater tuberosity on the anterior glenoid rim is also illustrated

It should be done at the earliest possible moment.

The principle of reduction is to make the head retrace its passage with the least possible further injury to the soft tissues

Three methods are available.

1. Gentle traction in abduction to 140 degrees and external rotation, i.e., the position of dislocation, associated with direct backward pressure on the head as the arm is adducted and internally rotated

2. Hippocratic method: Traction and adduction of the arm with the unbooted heel in the axilla as a fulcrum

3. Kocher's method: Long axis traction with the arm first externally rotated, then, while in forward flexion, adducted across chest and finally internally rotated

Postoperative Therapy.—The most certain way to prevent recurrence is by bandaging the arm to the side for 4 weeks and following this by re-education of the limb musculature and movements.

An alternative is to permit function of the joint but prevent for 4 weeks abduction above 90 degrees or external rotation. The power of the intrinsic muscles is maintained by resistance exercises in this range.

Fig 587—A, Posterior dislocation of right shoulder showing alteration in contour

B, X-ray showing anterointernal notch and posterior dislocation of shoulder (From Moseley, H F: An Atlas of Shoulder Dislocations, courtesy Abbott Laboratories)

Chronic Anterior Dislocation

Reduction has been accomplished up to 6 weeks following injury but after 3-4 weeks may be dangerous because of adherence of the axillary artery and brachial plexus to the productive scar tissue in front of the joint. If the patient is young enough to justify operative treatment, this would be carried out through the anterior approach to the joint. Should the dislocation be of long standing and function adequate, operation should be avoided.

Posterior Dislocation

Reduction can be effected by traction and external rotation in adduction associated with outward and forward pressure on the head secured by a fist or the unbooted heel in the axilla. There is a tendency to instability of reduction, and operative suture of the capsular defect may be indicated.

Recurrent Dislocation

Surgical treatment for this condition is becoming standardized. Repair of the capsule torn from the glenoid rim (Bankart) is per-

formed. Silk sutures through drill holes, staples, fascia (Gallie), bone graft, and metallic rim are different materials employed.

Complicated Dislocations

Dislocations may be complicated by fractures of the greater tuberosity, surgical or anatomic neck, lesser tuberosity, or glenoid rim. Diagnosis is made by x-ray examination.

The principle of treatment is the reduction of the dislocation and fracture as well. In the adult patient open operation is frequently needed.

Ruptures of the rotator cuff should be suspected in patients over 50 years who do not regain the power of abduction and in cases where the axillary nerve is intact as indicated by deltoid contraction against resistance. Operative suture is required.

Dislocations of the shoulder may be accompanied by nerve injuries:

1. Axillary nerve
2. Posterior cord
3. Complete brachial plexus

Sometimes nerve injury results from the excessive force used in reducing the dislocation. These nerve injuries usually recover on conservative therapy, as the injury is one of contusion or stretching.

Rupture of the axillary vessels has been noted, especially in manipulation of the chronic dislocation. Loss of limb and death have resulted.

LESIONS OF THE SOFT TISSUES

Ruptures of the Rotator Cuff

The term *rotator cuff* is applied to the musculotendinous envelope formed by the supraspinatus, infraspinatus, and teres minor attached to the greater tuberosity and the subscapularis attached to the lesser tuberosity. The former are external rotators, the last an internal rotator of the humerus. The tendons of these muscles fuse with the capsule before insertion on the humerus. They function as a fine adjustment in the shoulder mechanism.

Incidence.—Ruptures of the rotator cuff are frequent injuries in patients over 50 years but usually fail to receive adequate medical attention.

BICIPITAL LESIONS

ture or dislocation. The axillary nerve is not paralyzed. Procaine injection demonstrates marked weakness in attaining or maintaining abduction. The drop arm sign indicates massive rupture.

Treatment.—Unless contraindicated by age or general health, the ideal treatment is operative suture at the earliest moment. The tendon is sutured to a trough cut near its original insertion. Postoperative care consists of rest in an abduction splint or in a sling. It is best to repair in such a way that the limb can be in a sling without tension on the suture line. Early movements in the relaxed muscle position can be carried out, but active abduction, lifting the weight of the arm, should not be permitted for at least 4-6 weeks. The whole period of re-education requires 3-6 months, but the benefits of operation are most clearly seen after 1 year. When patients are seen at a late period with weak and painful shoulders and with restricted movement, a trial of the benefit to be obtained by re-education of the shoulder with pulley exercises should be carried out before reconstructive surgery on the torn tendons is considered.

Rupture of the Long Tendon of the Biceps

Rupture of the tendon of the biceps may occur in the intra-articular portion, at the junction with the muscle belly or at its insertion. The first is by far the commonest type.

Incidence.—As for ruptures of the rotator cuff, the biceps tendon is ruptured in the laboring class and in the age group over 50 years.

Mechanism.—The rupture may occur spontaneously from years of gradual attrition involving also the supraspinatus tendon. In other cases it occurs simultaneously with rupture of the supraspinatus tendon when a heavy weight is suddenly lifted above the level of the shoulder.

Clinical Picture.—The patient feels a sudden pain in the shoulder with a snap and notes a lump in the arm. The pain may be minimal in the attrition rupture in senile patients.

Examination reveals tenderness in the bicipital groove and restriction of shoulder movements. Crepitus is usually present on rotation

of the humeral head. Signs of rupture of the rotator cuff are noted.

On supination of the forearm against resistance, the belly of the long head will harden, showing loss of its elongated shape. When relaxed, the loss of the tension of the tendon permits increased mobility to the examining fingers.

Diagnosis.—Diagnosis is readily made on the history of injury and presence of the swelling in the arm. The possibility of concomitant cuff rupture must be considered.

Treatment.—In old patients, reparative treatment is elective. In the active laborer, suture of the tendon in the bicipital groove with plastic repair of the cuff is indicated. The patient should not be permitted heavy use of the limb for 8-12 weeks.

Recurrent Dislocation of the Biceps Tendon

This is a rare condition in which the tendon slips forward over the lesser tuberosity and occurs where repeated stretchings or one severe injury has weakened the bicipital sheath at the top of the groove.

Diagnosis.—This is made by feeling the tendon slipping forward as the humerus is externally rotated.

Treatment.—Therapy is directed to transection of the tendon and fixation of the distal end in its groove.

FRACTURES OF THE SHAFT OF THE HUMERUS

The shaft consists of that portion between the surgical neck and the condyles.

Mechanism.—These fractures may be caused by direct or indirect violence. The resultant injury is a transverse, spiral, or comminuted fracture.

The deforming forces are the fracturing violence and muscle pull.

Fractures occurring above the deltoid insertion have the upper fragment drawn inward by the pectoralis major and latissimus dorsi, whereas the lower fragment is displaced outward by the deltoid. Fractures below this level have the upper fragment drawn outward by the deltoid in relation to the lower fragment. The sling position most commonly used

Fig 590 - -Influence of muscular pull on fractures of the humerus at different levels

Fig 591 -A, X-ray of fractured humerus treated in hanging cast.
B, Clinical union with improved alignment.

for splintage places the lower fragment in internal rotation and adduction

Diagnosis.—The arm is useless in the complete fractures, with local tenderness, swelling, and deformity marking the site. Radiologic examination gives the exact details of the bony injury and should include three dimensional studies

Examination should include a study of the muscles supplied by the radial nerve. *Wrist drop* is the characteristic finding when this nerve is injured. (See Figs 152 and 153.)

Fig 592—Fractured humerus with injury to radial nerve

Treatment.—Conservative methods usually suffice. In spiral fractures and in the reverse fractures after manipulative reduction, a spica or sugar-tong cast is applied. In fractures in the lower half, a hanging cast can be used

When reduction has been unsuccessful, traction is employed

Traction methods are advised in small hospitals in preference to open operation with internal fixation. The latter is the method of choice in the hands of specialists when

manipulative reduction is unsatisfactory when injury to the radial nerve is present. The best approach is that of Henry extending along the outer aspect of the biceps. An intra-medullary nail is an alternative form of internal fixation but is less satisfactory.

The time for healing in fractures of the humerus is about 6-12 weeks, being less in the spiral type of fracture and in the young patient.

Complications.—Nonunion may occur in the transverse fractures in the upper and lower thirds as a result of inadequate treatment. Injury to the radial nerve is the most common complication. Stiffness of shoulder and elbow with vasomotor disturbance of the hand may occur. These are best prevented by functional use of the limb and avoidance of passive splinting

FRACTURES OF THE LOWER END OF THE HUMERUS

Supracondylar Fracture

This is the most common fracture of the lower end of the humerus and occurs most frequently in children and adolescents. The greatest incidence is from 5-8 years. This type accounts for over 50% of elbow fractures

Mechanism.—The force is usually indirect through the hand and forearm to elbow with posterior displacement of the lower fragment of the humerus. The elbow is almost completely extended

The reverse fracture may be produced by a direct blow from behind on the flexed joint

Post-Traumatic Anatomy.—The line of fracture runs upward and backward. The sharp lower end of the humeral shaft may injure the brachial vessels or median nerve. The lower fragment frequently presents a lateral or medial in addition to the posterior displacement

Clinical Picture.—The patient holds his elbow at 140 degrees. The differential diagnosis must exclude a posterior dislocation. Gross swelling may obscure the bony landmarks of the epicondyles and olecranon which are in their normal relations to each other in contradistinction to the findings in posterior dislocation. X-ray examination is conclusive

C CARRYING ANGLES OF THE UPPER LIMB

Fig 593.—Surgically applied anatomy of the elbow The epiphyses of the lower end of the humerus, except that for the medial epicondyle, fuse together at 14-15 years of age and finally unite with the shaft at 17-20 years of age. In each site the earlier dates indicate the time of appearance (in years) of the ossific center, whereas the later dates indicate fusion time

FRACTURES OF THE UPPER EXTREMITY

Fig. 594.—Diagram of supracondylar fracture with mechanism of Volkmann's contracture (After Bunnell.)

Fig 595—Supracondylar fracture of humerus with posterior and medial soft tissue shadow and almost completely extended position of the elbow
A, Anterior view. B, Lateral view

Treatment.—The surgeon's approach is determined by the following factors

- 1 Extent of displacement of the fragments
 - 2 Degree of swelling around the elbow
- This factor is a composite of the severity of the injury and the time interval since the accident.
- 3 Circulatory status of the peripheral part of the limb The radial pulse should always be

studied, as well as any signs of circulatory embarrassment such as pallor or cyanosis of the hand and fingers. Because of the possibility of Volkmann's ischemic contracture, all supracondylar fractures should be supervised in hospital.

If the patient is seen early and displacement is minimal, a posterior plaster slab or a sling alone, arranged to maintain the elbow in

Fig 596—A, Skeletal traction through olecranon, used in the adult for fractures of the lower end of the humerus

B, Dunlop's method for supracondylar fractures in the child, occurring especially in the age period 5-12 years. The traction is maintained after x-rays show good reduction and is continued until clinical union of the fragments is present and control x-rays show callus forming.

Countertraction in each case is applied by fixing the trunk to the mattress or opposite side of the bed.

FRACTURES OF THE UPPER EXTREMITY

flexion at less than a right angle, suffices. Gentle active movements may be initiated after 10-14 days. This group rarely gives complications.

If seen early but the displacement is marked, manipulative reduction at the earliest moment under general anesthesia, with radiologic control, is essential. The lateral or medial displacement is first corrected, and then gentle traction with direct pressure downward and forward on the olecranon is used to correct the posterior displacement. The axis of the forearm should be in the direction of the shoulder of the affected side, not in the direction of the opposite shoulder as often suggested. The latter will result in a cubitus valgus (gunstock) deformity. A posterior plaster slab is applied in the maximal flexion permitted by the circulatory condition. This is usually 10 degrees of flexion less than the point where weakening of the radial pulse is noted. The pulse is supervised for 24-48 hours following the manipulative reduction, and danger signals such as pain, pulse changes, pallor, or cyanosis are watched for. The patient is instructed to move the fingers at all times. Immobilization is maintained for 3 weeks. The maintenance of the reduction is checked by x-ray. Re-education of function follows.

If seen late and there is marked displacement associated with brawny swelling around the elbow, the circulatory status should be carefully noted. Most cases in this group should be treated either by skin traction, with the limb elevated and abducted from the side, or by skeletal traction through the olecranon, with the arm in the position of 90 degrees forward flexion. These methods are preferred to manipulation which may not secure or maintain adequate position and often accentuates the traumatic inflammatory reaction. Traction is maintained for 2-3 weeks, and the position is checked periodically by x-ray. Manual manipulations may be required to supplement the treatment by traction. When the traction is removed a collar and cuff or sling is applied and active exercise therapy begun. Traction should be the method employed in any case where the possibility of Volkmann's contracture developing is anticipated.

Fracture-Separation of the Lower Humeral Epiphysis

These epiphyseal injuries may involve.
The entire epiphysis
The lateral condyle or
The medial epicondyle

Lower Humeral Epiphysis

The lower humeral epiphysis consists of two ossific units for the capitellum and trochlea which unite around puberty. There is a further center for the medial epicondyle and an inconstant one for the lateral epicondyle.

Fig. 597.—X-ray of fracture-separation of lower humeral epiphysis with forward displacement

epiphysis with or without the medial epicondyle occasionally occurs before puberty, and the displacement is usually forward. This type of case is generally included with the supracondylar fractures, and the principles of treatment are identical. Cases which have presented the forward displacement require immobilization in extension to preserve the reduction.

Lateral Condyle

This is a serious epiphyseal injury occurring in children and adolescents. The fracture line separates the capitellum and lateral portion of the trochlea together with the lateral epicondyle and common extensor origin.

A.

B.

C.

D.

Fig 598.—Posterolateral dislocation of the left elbow with inclusion of the medial epicondyle within the joint

A and B, Anteroposterior and lateral views before reduction. Note position of the fragment of the medial epicondyle.

C and D, Similar views after reduction and fixation of the medial epicondyle by Kirschner wire

Displacement may be minimal or there may be lateral displacement alone or a rotatory element may be produced by the pull of the extensor muscles

In patients with minimal or lateral displacement, manipulative reduction may be adequate. Plaster immobilization for 3 weeks can be utilized

When the lateral displacement cannot be corrected by manipulation, in those patients presenting displacement but seen several days after the accident, and in most patients presenting a gross deformity due to rotation, open operative reduction and internal fixation, using one or more fine Kirschner wires, are necessary. The wires are removed after 3-4 weeks.

Fig 599 --Intercondylar T fracture of humerus

Even after operative reduction, growth disturbances tend to occur. Premature closure of the lateral condylar epiphyseal line with overgrowth of the medial condylar element produces a cubitus valgus deformity. A late complication after 10-20 years is secondary ulnar palsy

Medial Epicondyle

Avulsion of the medial epicondylar epiphysis occurs as a result of valgus strain of the elbow and usually complicates postero-

lateral dislocation of this joint. When minimally displaced, no special treatment is necessary. However, when grossly displaced by pull of the common flexor muscles, or when retained within the joint after reduction of the dislocation, or when associated with injury to the adjacent ulnar nerve, open operative reduction and internal fixation are required. Transposition of the ulnar nerve may be necessary.

Condylar Fractures

Fracture of the medial or lateral condyle or both occurs in the adult as a result of direct or indirect violence. The fracture most frequently involves the lateral condyle.

Fig 600 --Lateral condylar fracture

Patients with minimal displacement require rest for 3 weeks. In the displaced fracture, accurate anatomic reduction is indicated at the earliest moment, and this is best carried out by open operation and internal fixation

Two types of lateral condylar fractures are described. The *unstable type* presents a lateral subluxation since the fractured fragment includes the lateral lip of the trochlea, and the greater sigmoid notch is not stabilized on the remainder of the trochlea. In this type the ulnar collateral ligament is ruptured.

The *stable type* does not show the lateral subluxation, as the lateral lip of the trochlea is not separated

In both types operative reduction is indicated when displacement is present. Internal fixation should secure anatomic reduction of the articular surface, and in the unstable type suture of the collateral ligament is also required

Operative procedures on these fractures often lead to aseptic necrosis of the fractured fragment, and secondary procedures may be necessary. For this reason, in the stable type the fragment, if completely separated from its blood supply, should be removed primarily.

In supracondylar, dicondylar, and comminuted fractures of the lower end of the humerus in adults, skeletal traction, excision of devascularized fragments, or a combination of both procedures may be indicated.

Kocher's Fracture

This rare but important fracture consists of the separation of a semilunar fragment of articular cartilage and bone from the capitellum. This may be associated with other fractures of the elbow such as that of the radial head. The fragment is usually displaced into the front of the joint.

Diagnosis is by x-ray, and the treatment is by excision of the fragment.

Fractures of the Epicondyles

Fractures of the epicondyles occur in the young, as epiphyseal separations, or in the adult, from direct violence or by avulsion. The medial epicondyle is the more frequently separated. Conservative therapy suffices except in gross displacement of the medial epicondyle with injury of the ulnar nerve when operative intervention is indicated. This consists of anterior transposition of the nerve with removal or internal fixation of the fragment. When the epicondyle is retained in the joint after reduction of a dislocation, faradic stimulation of the flexors usually secures reduction.

Open operative reduction and suture or removal of the bony fragment often constitute the best treatment.

FRACTURES OF THE HEAD AND NECK OF THE RADIUS

Fractures of the head of the radius are disabling because of the subsequent limitation of pronation and supination of the forearm and hand. They are often associated with dislocation of the elbow.

Mechanism.—Fractures result from indirect violence through the hand transmitted up the radius to the head which is impacted on the capitellar surface of the humerus. Direct violence may also cause fractures to the head alone or to all bones forming the elbow joint.

Post-Traumatic Anatomy.—Radiologic examination indicates the fissuring of the bone, but the cartilaginous damage of the radius and capitellum must be surmised. The types of fracture are indicated in the diagram.

Diagnosis.—This is made by noting the swelling over the head of the radius together with local tenderness and pain accentuated by rotation. X-rays are conclusive and indicate the extent of the injuries.

Treatment

Separation of the Upper Radial Epiphysis.—The typical radial and anterior angulation is shown in Fig. 601. When the angulation is less than 60 degrees, manipulative reduction under general anesthesia should be performed. This consists of placing the elbow in extension, forcing the joint into varus to open up the lateral joint space, and applying direct pressure on the head in a posterior and medial direction, correcting the displacement. Radiologic examination in the operating room will indicate the result. In cases where adequate correction has not been attained or where the original displacement was more severe, open operation and gentle replacement should be performed. On no account should the radial epiphysis be removed before the age of 15 years, as this leads inevitably to growth disturbances at the elbow and wrist. Restriction of pronation and supination is the invariable sequel. Immobilization in full flexion for 10-14 days is required following operation.

Fracture of the Neck of the Radius.—In the presence of marked displacement, operation is indicated. If the head can be anatomically

replaced and sutured, this should be done. Usually in the adult the whole head and the loose fragments must be removed and the neck covered with soft tissue to give a smooth surface.

Fractures of the Head.—Fissured fractures without displacement require immobilization in flexion for 3 weeks to allow healing of the fractured joint surface and fixation of loose fragments of cartilage.

Fissured fractures with displacement and comminuted fractures are best treated by resection of the head and removal of all loose fragments at the earliest moment. Postoperative therapy consists of gentle movements, but

traumatic arthritis is minimized by avoiding heavy work for 6-12 weeks.

FRACTURES OF THE OLECRANON

Mechanism.—Fractures of the olecranon may be caused by indirect violence through the triceps or by a direct blow to this prominence.

Post-Traumatic Anatomy.—This injury should be compared with that of the patella. Both involve the extensor mechanism of a hinge joint. The indirect type of fracture is transverse, and when separation is present the aponeurotic attachment of the triceps on each

Fig 601.—Types of fracture of head and neck of radius

side is torn. Direct violence results in a comminuted type of fracture.

Diagnosis.—Clinically the area is swollen and tender. The gap between the fragments may be seen or palpated.

Treatment.—Stable transverse or comminuted fractures without displacement may be treated by early function associated with local hot moist applications to diminish the swelling.

Fractures with separation require exploration and suture. Suture should include the aponeurotic tear as well as the osseous fragments. In the older patient excision of the fragments is often the method of choice. Excision is definitely contraindicated when the

COMPLICATED INJURIES OF THE ELBOW

All varieties of injury are found in this region. One of the most difficult is that in which the projecting elbow is struck by a passing vehicle—so-called "sideswipe" fracture. This may be compound and usually consists of a comminuted fracture of all three bones.

LESIONS OF THE SOFT TISSUES

Myositis Ossificans

This is one of the most common complications of injuries of the elbow. Operations required for such trauma should be performed at the earliest moment. When undertaken after the 4th day the probability of myositis ossificans ensuing is greatly increased. The anterior capsule, brachialis anticus insertion, and annular ligament are most frequently involved (See general section on Fractures.) The condition is aggravated by passive movements, especially by forcible extension in the early stages after injury.

Treatment.—Function may be encouraged while the range of motion is increasing. When suspected, the course of the ossification should be followed by repeated x-rays, and gentle active movements only must be permitted. If the patient is seen late with a dense area of calcified tissue limiting motion, operative removal must be considered.

Volkman's Ischemic Contracture

This occurs most frequently after elbow injuries and is due to an interference with the circulation of the forearm muscles. The cause may be a spasm of the brachial artery or an obstruction to the venous return.

Treatment.—Prevention by early reduction of dislocations and displaced fractures and by elevation of the limb to encourage venous return is best. When the onset is suspected, because of pain in the forearm, swelling of fingers, and absent radial pulse, hot moist packs and sympathetic block may help. If this fails, exposure of the vessels is required. Excision and replacement of the damaged brachial artery may be necessary.

Fig 602—Separated fracture of olecranon

fracture is sufficiently distal to permit anterior subluxation of the ulna. Internal fixation with an intramedullary nail is the treatment of choice in such cases.

Immobilization may be in a sling or light plaster cast at 90 degrees. Movements may be encouraged at an early stage, 7-10 days, and excellent results are obtained in 6-12 weeks.

Fig. 603—*A*, End result of fracture-dislocation of elbow which developed traumatic arthritis with myositis ossificans

B and *C*, Postoperative x-rays after resection of the deformed radial head and calcified soft tissues

Seddon's idea of resection of the ischemic muscle infarct, involving chiefly the flexor digitorum profundus and flexor pollicis longus, after an interval of 3-4 months to observe recovery affords considerable promise.

After the chronic contracture is established, even extensive reconstructive surgery leaves considerable impairment of function.

Secondary Ulnar Palsy

This follows fractures of the lateral condyle in the young with premature synostosis and development of cubitus valgus. The ulnar

Tennis Elbow

Tennis elbow is a clinical syndrome with several underlying causes.

It is characterized by tenderness over the lateral epicondyle and pain radiating over the extensor aspect of the forearm. There is weakness and pain on extending the wrist against resistance, and any use of the limb accentuates the discomfort.

The lesion is a sprain of the common extensor origin and may be associated with deposition of the phosphate and carbonate of calcium. Rest together with heat and salicylates

Fig 604—Syndrome of tennis elbow caused by calcified deposits in the common extensor origin.

A, Supination

B, Pronation. Note pressure of orbicular ligament on deposit.

nerve is gradually involved in a traumatic neuritis which develops years after the injury. Clawing of the 4th and 5th fingers, with typical sensory changes, is present.

Treatment consists of anterior transposition of the ulnar nerve.

is effective usually. Local needling of the point of maximum tenderness under local anesthesia, followed by infiltration of the area with 1 ml hydrocortisone, frequently produces a cure. If the condition becomes chronic, subperiosteal resection of the common extensor origin is the

best therapy. Calcified material should be removed

Stiff Elbow and Traumatic Arthritis

This is an all too frequent complication of elbow injuries. The elbow is a closely fitting joint and does not react favorably to intra-articular trauma. All operative procedures should remove any mechanical irregularity or loose fragment. This joint does not permit passive movements of a forcible character which usually result in increasing stiffness. It should, if possible, be splinted in flexion above the right angle, and in re-education the progress should be accurately charted after measurement of range by the goniometer. Unless the range is progressively increasing without loss of flexion, the therapy is either being instituted too early or is excessive. There may be an intra-articular derangement causing delay in progress, and the condition should be reviewed.

DISLOCATIONS OF THE ELBOW

Dislocations occur in this joint more commonly in the young and as a result of indirect forces transmitted through the forearm and hand. The majority (80%) are posterior dislocations and may be complicated by fractures of the medial epicondyle, head of the radius, or the coronoid process.

Posterior Dislocation

Mechanism.—Posterior dislocation is caused by a fall on the outstretched hand, the force being transmitted upward with the elbow dislocating by sudden hyperextension and contraction of the triceps.

Post-Traumatic Anatomy.—The displacement of the ulna is upward and backward. The coronoid process may be fractured. The capsule is torn anteriorly and on each side from the humerus.

Clinical Picture.—The patient holds the painful and swollen elbow at 140-160 degrees. Flexion is impossible. The relation of the epicondyles and olecranon is altered, and the olecranon process is very prominent. X-ray examination indicates the displacement and associated fractures.

Reduction is best effected under general anesthesia. Gentle traction on the hand with the elbow at 160 degrees, with direct pressure on the displaced olecranon in a downward and forward direction, usually reduces the displacement with ease. The limb should be splinted in as much flexion as the circulatory state will permit. Dislocations of more than 2 weeks' standing usually require open operative reduction.

FIG. 605.—Patient with posterior dislocation.

Postoperative Therapy.—Gentle active movements can be carried out almost immediately as the reduction is stable. Movements should consist of active flexion. If the range of motion progressively increases, function may be augmented. A full range may be secured in 1-6 weeks. Alternatively, plaster immobilization in the flexed position for 3-4 weeks may be employed.

Posterolateral Dislocation

This differs from the above in the lateral displacement, and x-rays may show avulsion of the medial epicondyle. After reduction, the

Fig 606.—Posterior dislocation of elbow

Fig 607.—Monteggia fracture dislocation

medial epicondyle sometimes remains within the joint. Operation with suture or removal of this fragment and with anterior transposition of the ulnar nerve is then indicated. The ulnar nerve may be injured in this dislocation. These patients are best treated in plaster casts as the reduction may be unstable.

Subluxation of the Radial Head (Pulled Elbow)

The radial head and neck are of approximately the same size up to the age of 8 years. Before this time a sudden pull by the parent or nurse on the child's limb subluxates the radial head distally out of the orbicular ligament, with resultant pain and limited elbow function.

On examination the forearm is held in mid-rotation. Any attempt at movement of the elbow, especially with supination of the forearm, is resisted. Radiologic examination is negative for demonstrable displacement.

The subluxation is corrected with a definite click when the forearm is quickly supinated with or without the assistance of general anesthesia.

Monteggia Fracture-Dislocation

It is one of the injuries around the elbow most frequently overlooked and at the same time most difficult to treat.

Mechanism.—The injury results from a fall against an object which acts as a wedge, fracturing the upper third of the ulna, and as the force carries on, the pronated radius is levered forward, rupturing the annular ligament.

Post-Traumatic Anatomy.—This consists of a fracture of the upper third of the ulna with the fragments angulated forward associated with an anterior dislocation of the head of the radius with ruptured annular and radio-humeral ligaments. The biceps tendon tends to maintain this displacement.

Diagnosis.—Such a complicated injury should be suspected in all fractures of the upper third of the ulnar shaft. X-ray examination should be carried out to confirm the diagnosis.

The opposite displacements occur rarely when the violence is in reverse direction.

Treatment.—Early cases should be treated by operative reduction, internal fixation of the fractured ulna, and suture of the annular ligament. Boyd's posterolateral incision is used. The elbow is splinted in flexion and supination for at least 3-4 months.

Late cases with nonunion require open reduction with bone grafting of the ulna and excision of the radial head. If malunion is present, resection of the head of the radius may be necessary to improve pronation and supination; reconstruction of the ulna is not usually indicated.

FRACTURES OF THE FOREARM

Fractures of the forearm may involve one or both bones and are caused by direct or indirect violence. The site of fracture may be in the upper, middle, or lower third, the frequency increasing distally.

Mechanism.—A fall on the outstretched hand is the usual cause. When both bones are broken, the distal fragments are dorsally displaced. Direct violence generally gives a transverse fracture, and if both bones are broken, the fractures are usually at the same level.

Post-Traumatic Anatomy.—In the young, the greenstick type of fracture is common, and considerable angulation is present. In the adult, wide separation is possible.

In fracture of one bone, it must always be remembered that overriding of the fractured ends can occur only with subluxation or dislocation of the other bone at the superior or inferior radioulnar joint. In fracture of the radius, muscular forces must be considered in analyzing the displacements. *Fractures above the pronator teres* have the upper fragment flexed and supinated by the biceps and supinator, whereas the lower fragment is pronated and displaced toward the ulna by the pronator teres and pronator quadratus. *In fractures below the insertion of the pronator teres*, the upper fragment is flexed and supinated to a minor degree, and the lower fragment is displaced toward the ulna. *In fractures in the lower third*, the distal fragment of the radius is pronated and drawn toward the ulna by the pronator quadratus.

In injuries caused by direct violence, the direction of the force is the determining factor in the displacement.

The mechanics of the post-traumatic anatomy of forearm fractures is of the greatest importance. The greenstick fractures, if carefully reduced, are usually stable. Fractures of one or both bones in the adult are prone to re-displacement after reduction unless the fractured surfaces solidly interlock. This tendency to instability after reduction is the reason why fractures in this area are especially suitable for open operation and internal fixation.

Diagnosis.—Diagnosis is readily made in cases of angulation or gross displacement. X-rays in two planes are essential.

Treatment.—From the point of view of therapy the fractures may be divided into (1) greenstick fractures, (2) fractures without displacement, and (3) fractures with displacement.

Greenstick fractures are manipulated under general anesthesia by traction and direct pressure over the point of angulation. The angulation is just overcorrected. Great care must be

Fig 608—Influence of muscle pull on fractures of the radius, at different levels.

taken to avoid complete fracture and displacement.

A cast is applied from axilla to metacarpal heads with elbow at 90 degrees, forearm in mid-position, and wrist slightly dorsiflexed. Fractures of one or both bones without displacement are placed in the same type of cast. The time of immobilization varies from 6-12 weeks.

tained and a cast applied. The possibility of redisplacement must be checked by repeated x-ray. The cast is changed when the swelling subsides. Thumb traction associated with the cast may prevent some cases of recurrent displacement.

Open operation and fixation of the one bone in single fractures and both bones in dual fractures is the safest and best method

Fig 609—Typical x-rays of fractured radius before and after plating

Fractures with displacement are treated by (1) manipulation and plaster cast, (2) open operation and internal fixation, and (3) external skeletal fixation

Manipulation under a general anesthetic with fluoroscopic or x-ray plate control is the safest method. Stable reduction must be ob-

in the hands of the specialist. Postoperative fixation in a cast is required for 2-3 months. Plates may be removed when union has occurred

Intramedullary fixation has been used in fractures of these bones and is best for fractures of the ulna. External fixation by two pin

units of the Roger Anderson or Stader type can be used by those working routinely with this method. Open operation with plating is advised in preference to this method.

Complications.—*Malunion* is common in forearm fractures because of factors mentioned above, together with the longer period required for consolidation in these bones.

Fig 610—X-ray of cross union

Cross union may occur because of the tendency of the bones to approximate each other after fracture. This tendency is diminished by splinting in mid-pronation, at which point the bones are farthest apart. Both *malunion* and *cross union* have their chief disability in limiting the range of pronation and supination. *Delayed* and *nonunion* are fairly frequent.

Dislocation of superior radioulnar joint may persist after fracture of the upper third of the ulna in Monteggia fracture-dislocation.

Dislocation of inferior radioulnar joint may result from fracture of the radius with overriding or as a concurrent injury. If disabling, resection of the lower inch of the ulna gives considerable improvement in function.

FRACTURES OF THE WRIST

Fractures of the lower end of the radius, with or without injury to the articulating bones, constitute the largest group of cases attending traumatic clinics. These injuries occur at all age periods but are most frequent during the active period of life. In northern climates they increase during the winter months.

Mechanism.—The usual cause is a fall on the outstretched hand.

Post-Traumatic Anatomy.—The typical deformity described by *Colles* consists of three parts. The lower fragment is displaced (1) posteriorly, (2) radially, (3) with its articular surface rotated to face more dorsally.

If the radial displacement is sufficient, the ulnar styloid is avulsed with the ulnar collateral ligament. This triple displacement constitutes the dinner-fork deformity. The reverse deformity with forward displacement is called *Smith's fracture*.

All cases, however, do not fall into this type and the variations are legion. It probably leads to poor work to classify all these cases as *Colles' fractures*, and each must be analyzed and treated as an entity.

In the young adolescent, separation of the lower radial epiphysis, usually through the metaphysis, is the common injury. In older patients, a comminuted impacted fracture with foreshortening of the radius in relation to the ulna is common.

The most important factor in functional restoration is the mechanical alignment of the inferior radioulnar joint.

Derangement of this mechanism results in a limitation of pronation and supination, the latter being that more commonly limited.

Diagnosis.—This is made on the typical deformity when present, the local tenderness, and radiologic findings.

A

Fig 613—A, Diagram shows the bony displacement and clinical appearance in a typical Colles' fracture with posterior and radial displacement. Note the so called dinner fork deformity as shown in the lateral view.

B, Malunion of a Colles' fracture. Note the radial displacement of the whole hand and the prominence of the lower end of the ulna.

Treatment.—Fractures without displacement should be treated in a functional cast permitting all movements of the digits. Time factor 3-6 weeks.

Fractures and epiphyseal separations with displacement are best reduced by the Helferich or handshake method. The essentials are traction and countertraction for 3-5 minutes under

general or local anesthesia. Following this displacement, the lower fragment is compressed volarward and toward the ulnar side. It is almost impossible to overcorrect a Colles fracture, and adequate reduction of the triple displacement is essential. Both uncorrected displacements and foreshortening will give a derangement of the inferior radioulnar joint with interference to perfect rotation.

Fig. 614—Type fractures of lower end of radius

Smith's fracture is the reverse of Colles fracture. The lower fragment of the radius with the hand is displaced volarward. The mechanism is a hyperflexion injury or direct blow in a forward direction on the dorsum of the hand.

Barton's fracture is a posterior fracture subluxation of the carpus with separation of a large fragment of the posterior articular surface of the radius. This lesion is typically unstable.

Chauffeur's fracture, so-called from the days before the push button starter in the motor car, was produced by the backfire and sudden reverse of the crank handle. It consists of a fracture separation of a large lateral fragment of the radius with the styloid process.

Separation of the lower radial epiphysis, usually with a triangular fragment of the diaphysis, occurs in the young before closure of the epiphysis at 18-21 years. The displacement occurs most commonly posteriorly but may be anterior.

The essential point to ascertain after reduction is whether the reduction is stable. The vast majority of correctly reduced fractures are stable and can be immobilized in a neutral position. (See general section on Fractures.) Probably not more than 15% are unstable as indicated by the tendency to immediate displacement after manipulation

Reduction is successful up to 10-14 days. After this period refracture by closed or open procedures may be necessary in the younger patients.

After removal of the cast, exercises to restore pronation and supination as well as the function of the whole limb are indicated.

Fig 615—X ray showing the osteoporosis of Sudeck's atrophy with normal hand for comparison

These latter should be immobilized in volar flexion of 10-20 degrees and ulnar deviation. The Cotton-Loder position of full volar flexion is not recommended, because of the tendency to circulatory interference. The typical functional cast should be applied. In the comminuted fractures and in unstable reductions, limitation of elbow movements by inclusion in the cast for 2 weeks is desirable. The average period for plaster splintage is 4 weeks, and during this period, active movements of the fingers are necessary. Elevation of the limb postoperatively to diminish swelling is required.

Complications

Malunion.—Many cases are seen where failure to secure adequate correction of the radial deviation has occurred. Most symptoms relate to the inferior radioulnar joint, although many cases have function which is surprising in view of the deformity. Resection of the lower inch of the ulna will improve some of these cases.

Sudeck's Atrophy.—Post-traumatic bone atrophy occurs most frequently after injuries at the wrist. With the earliest sign of painful swelling and stiffness of the fingers, the cast must be split, the limb elevated, and active

movements of all fingers encouraged. This usually succeeds in arresting the vasomotor disturbances. Should these measures fail, procaine injection of the inferior cervical ganglion should be considered.

Rupture of the Extensor Pollicis Longus Tendon.—This may occur some weeks after the Colles' fracture from injury at the time of the fracture and subsequent attrition.

FRACTURES OF THE SCAPHOID

Fractures of the carpal bones are not common. Injuries of the scaphoid are the most frequent and most important. Neglect of early recognition and immobilization leads to painful nonunion and traumatic arthritis.

Fig. 616.—Type fractures of the scaphoid in relation to the vascular supply

The other carpal bones may be involved in sprain fractures or comminuted by direct or indirect violence. Such cases are rare and are discovered on radiologic examination.

Mechanism.—Fractures of the scaphoid are caused by falls on the outstretched hand with dorsiflexion and deviation to the radial or ulnar side. Fracture through the waist occurs when the two poles are locked and compressed. Forced ulnar deviation may cause a sprain fracture of the tuberosity.

Post-Traumatic Anatomy.—The common injury is a fracture through the waist. Sometimes the line of fracture passes more proximally, giving a small ulnar fragment. The importance of this rests on the fact that the vascular supply to the scaphoid enters on a narrow area on the dorsal aspect of the bone and, in the cases with a small ulnar fragment, this portion of the bone may be devoid of circulation and undergo avascular necrosis. These are prone to nonunion. In certain cases of waist fractures, the radial fracture is displaced and this is often overlooked.

Diagnosis.—All sprains of the wrist with tenderness localized to the radial side of the joint and pain on dorsal or radial movements must be regarded as fractures of this bone until proved otherwise by radiologic examination in anteroposterior, lateral, and especially oblique planes. If the x-ray is negative and the clinical symptoms and signs persist, x-rays must be repeated in 10-21 days. Often a narrow fracture line may be overlooked, with inevitable nonunion.

Differential diagnosis from bipartite scaphoid is made by the even line between the fragments and the bilateral presence of this congenital anomaly.

The fracture line in the fresh case is usually narrow; after 10-21 days it appears broader because of the hyperemic decalcification. Cystic areas appear after 6-21 weeks, and sclerosis may be present after 4-6 months. Ischemic necrosis of the small ulnar fragment may be noted after 3-4 weeks by the relative density of this fragment in comparison to the radial fragment which is undergoing the decalcification of disuse.

Treatment.—Fractures of the tuberosity require only palliative therapy and give little disability.

All fresh fractures of the body require immobilization in a cast which places the wrist and thumb in the position of grasp. The thumb is best immobilized up to the interphalangeal joint (See general section on Fractures). Cases with displacement of the radial fragment need forcible manipulation through the full range of movement. The cast may be removed after 6 weeks, and progress of union should be determined by x-rays. Some cases in young adults may join in 8 weeks, but 16 weeks is more nearly the average. Union is determined when complete obliteration of the fracture line occurs.

If x-rays show ischemic necrosis of the ulnar fragment, two courses are open:

- 1 Continued plaster immobilization which may require 12-24 months
- 2 Removal of the ulnar fragment

There is no unanimity of opinion on this point and the case must be judged on economic

and other bases. The conservative approach is the best in most cases, and in clerical and professional personnel nonunion may be accepted and is often asymptomatic.

Cases of delayed union or nonunion, with pain interfering with work, may be treated by drilling, bone graft, replacement by spherical prosthesis, or arthrodesis of the wrist.

Post-Traumatic Anatomy.—The forced hyperextension of the hand on the forearm causes the hand with the carpus to displace dorsally, leaving the lunate bone in its normal position. This is called a *perilunar dislocation of the carpus*. Sometimes the navicular bone remains beside the lunate, giving a *perilunar-navicular dislocation*. If a concomitant fracture of the navicular occurs, the ulnar fragment usually

Fig. 617—A, Fracture of the scaphoid tuberosity. B, X-ray showing the faint fracture line of fractured scaphoid associated with Colles' fracture.

C, Aseptic necrosis with increased density of ulnar fragment.

D, Nonunion of fractured scaphoid. Note sclerosis of bone fragments, also osteophytic changes on proximal fragment and styloid process of radius, indicating traumatic arthritis.

DISLOCATIONS OF THE CARPUS

Dislocations of the carpus are uncommon, and most occur in relation to the lunate and scaphoid bones, although carpometacarpal and other dislocations occur from unusual direct or indirect violence.

Mechanism.—The cause is usually a fall on the outstretched hand or forced hyperextension of the wrist. Complicated fracture-dislocations result when the hand is caught in machinery.

remains with the lunate, and the radial fragment displaces posteriorly with the carpus, resulting in a *perilunar transnavicular dislocation*.

Thus is the first stage in the mechanism, since if forward recoil of the hand ensues, the proximal part of the os magnum impinges on the posterior cornu of the lunate and ruptures the posterior radiolunate ligament. The lunate bone is then displaced forward, rotating around

the anterior radiolunate ligament. The carpus has now returned to its normal position and produced an *anterior dislocation of the lunate*. If the navicular remained in whole or in its ulnar part with the lunate, this bone would be displaced forward as well, giving an *anterior dislocation of the lunate and navicular* or *anterior dislocation of the lunate and ulnar half of the navicular*.

the hand in the first stage of the anterior position of the semilunar on palpation in the second stage. Radiologic examination is essential, and in the lateral view attention is best concentrated on the proximal articular surface of the os magnum which normally fits into the concave surface of the lunate. In such dislocations these articular surfaces are completely displaced from each other.

Fig. 618.—Dislocations of the carpal bones. In the upper series of drawings, the bones indicated in black are those displaced, and the displacement is dorsally. In the lower series the carpal bones indicated in black are those displaced, and the displacement is volarward.

A chip fracture of the posterior cornu of the lunate may be present or a marginal fracture of the radius most commonly on its posterior rim. When the semilunar bone is dislocated anteriorly, pressure on the flexor tendons and median nerve is present.

Diagnosis.—The diagnosis may be suspected because of the dorsal displacement of

Treatment.—Reduction is achieved at the earliest moment under the full relaxation of general anesthesia. In the perilunar dislocations, reduction is easier than in the second stage. Long axis traction followed by direct pressure forward on the carpus while one finger firmly presses the *semilunar backward from the volar aspect of the wrist* results in

Fig. 619.—X-rays of perilunar dislocation of the carpus

A and *B*, Perilunar dislocation of the carpus in anteroposterior and lateral views. Note the comminuted intra-articular fracture involving the radial and dorsal aspects of the lower end of the radius

C and *D*, Corresponding views 5 months later. Note the aseptic necrosis of the semilunar bone. In the lateral view, the student should learn to recognize the articulation of the os magnum with the semilunar bone

Fig. 620—Dislocation of lunate and proximal half of scaphoid
A and B, Preoperative views

C and D, Several months following reduction performed 4 days after the accident. Note the aseptic necrosis of the lunate and proximal half of scaphoid. Also the failure of complete reduction of the fractured scaphoid and sclerosis of the fracture line.

reduction and prevents this stage from being converted into the more difficult second stage.

In the anterior dislocation of the lunate, long axis traction with the hand gradually dorsiflexed is required to open up the space for the lunate. Direct pressure on the posterior pole in a distal and posterior direction will make this bone retrace its steps.

This dislocation may be reduced by closed methods up to 10-14 days; after this time open

quired, and the time factor will be determined by x-ray evidence of union.

Most of these cases require a firm wrist strap protection when work is begun.

METACARPAIS

Fractures

Mechanism.—Fractures of the metacarpals are common and important injuries. They frequently result from a blow delivered by the fist or from a fall on the outstretched hand.

Fig 621—Kienbock's disease. Idiopathic aseptic necrosis or osteochondritis of the semilunar bone.

Fig 622—X-ray of Bennett's fracture dislocation.

operation is usually required. If this is done within 3-4 weeks, the bones may be replaced, later than this the fragments may be devitalized and are probably best removed.

In dislocations without fracture of the scaphoid, immobilization in a functional cast for 3 weeks is sufficient. When a fractured navicular is present, 8-12 weeks may be re-

Fig 623—X-ray of fractured metacarpals.

Direct violence may be the responsible factor, and crushing violence resulting in compound injuries are all too common among industrial accidents.

Post-Traumatic Anatomy.—When the force is directed along the adducted thumb as in boxing, the inner limb of the saddle-shaped base of the first metacarpal is sheared

off against the greater multangular bone. This permits the carpometacarpal joint to dislocate outward and backward and results in the most common metacarpal injury, i.e., *Bennett's fracture-dislocation*. (See Fig. 552, G.)

Should the force be received directly on the flexed 5th finger and the knuckle, an impacted fracture of the neck of this metacarpal results. The head in this case is displaced forward on the neck, and there is usually a noticeable deformity. This injury is second in frequency among metacarpal injuries.

The shafts of the metacarpals may be fractured in spiral or transverse manner, and an important complication is the hematoma which frequently develops on the palmar and dorsal aspects of the hand.

Treatment.—Bennett's fracture-dislocation requires careful treatment to secure good results, and the instability of reduction must be overcome by two methods:

1. Long axis traction in moderate abduction
2. Direct pressure medially on the base of the metacarpal

Traction and splintage are required for 4 weeks. Failure to carry out this treatment results in enlargement of the joint, with pain and development of traumatic arthritis.

Follow-up studies of this particular fracture-dislocation have shown that the frequent result is an enlarged, painful joint due to malunion. Moberg has therefore recommended open operative reduction by reflection of the

Fig. 621—Splinting of fracture of proximal phalanx

Diagnosis.—Diagnosis of Bennett's fracture-dislocation is made by the painful swelling with deformity and crepitus in this area. It is to be differentiated from a transverse fracture of the base of the metacarpal which is not an intra-articular fracture and which is stable on reduction. X-rays will show the triangular medial fragment in the Bennett fracture-dislocation.

Local tenderness, posterior angulation in the shaft fractures, and loss of the oleprominence in neck fractures are clinical findings in other injuries.

thenar muscles and fixation by a Kirschner wire removed after 3-4 weeks.

Fracture of the base of first metacarpal is usually impacted with the distal fragments in the adducted position. Direct pressure over the external angulated prominence associated with long axis traction produces a stable reduction. The thumb should be splinted in a well-molded plaster cast for 3 weeks.

In dislocation of the neck of fifth metacarpal, if the head is displaced with considerable forward displacement, reduction is obtained by direct pressure on the meta-phalangeal joint.

to a right angle and pushing forward on the shaft fragment while pushing back on the flexed finger. The fracture should be splinted to maintain position with these two opposing pressures or by longitudinal wire fixation.

Spiral fractures of the shafts are not usually seriously displaced. The hematoma on the palmar and dorsal aspects is a frequent complication, and the discomfort is best relieved by elevation, repeated hot baths, and gentle active finger movements. Unless the fracture is very painful and requires protection from blows, no splint is required. When indicated a closely molded plaster cast can be applied which extends to the knuckles and leaves the fingers free.

Transverse fractures of the shafts without displacement can often be treated by early gentle movements and hot baths to assist absorption of the hematoma.

ment is hyperextended and the proximal fragment flexed. Treatment consists of manipulation of the fragments into the correct alignment and maintenance with the finger flexed and long axis traction arranged to line up with the scaphoid tuberosity. Three weeks of elastic traction are required, during which period the other digits are constantly and actively exercised.

Crush injury of distal phalanx is one of the most common hand injuries. Most cases are compound fractures with severe damage to the soft parts.

In the average case, careful cleansing in saline solution followed by local application of a penicillin dressing and splinting will suffice. The minimal use of sutures is advocated. If possible, the nail is left as a splint.

Fig. 625 -Mallet finger

Transverse fractures with displacement require manipulative correction and plaster splintage. Incorporation of traction on the corresponding flexed fingers may be required to maintain position. When closed manipulation fails, open operative correction without internal fixation can be safely advised. Only a small dorsal incision is required to permit replacement and interlocking of the fragments.

PHALANGES

Fractures and Other Injuries

Fracture of the proximal phalanx is that which gives most difficulty. The interossei and lumbricals attached to the dorsal aponeurosis buckle the fragments so that the distal frag-

ment is hyperextended and the proximal fragment flexed. Treatment consists of manipulation of the fragments into the correct alignment and maintenance with the finger flexed and long axis traction arranged to line up with the scaphoid tuberosity. Three weeks of elastic traction are required, during which period the other digits are constantly and actively exercised.

Mallet or Dropped Finger.—Mallet finger results when the terminal phalanx is suddenly flexed while the extensor mechanism is taut. It frequently occurs in baseball and cricket players, but the housewife may present the deformity after stubbing the digit. The extensor tendon may be torn off the base of the distal phalanx with or without its bony insertion.

Treatment to be effective must be carefully followed and may be one of two types.

1 Splinting in a plaster cast without interruption for 6 weeks with the distal joint hyperextended and middle joint flexed

2. *Suture with removable suture* placed through the phalanx. The hyperextension of the joint is best maintained by a longitudinally placed Kirschner wire

If either of these methods from the outset appears impractical, the hand may be permitted full movements with protection from strain or injury and will heal with some flexion deformity and stiffness of this joint. This is

placed posteriorly. Such dislocations most frequently occur in the thumb, and the head of the metacarpal is buttonholed on each side by the two heads of flexor pollicis brevis

Reduction.—Reduction is usually possible by hyperextending the thumb and maintaining traction, drawing the digit from side to side while exerting lateral and posterior pressure on the metacarpal head.

If closed reduction fails, dorsolateral incision is made and the buttonhole opened to permit reduction.

Fig. 626 -- Backward dislocation of thumb

all too frequently the end result from failure to splint in the correct position for the time indicated.

The joint should be splinted for 7-10 days in a flexed position. This is followed by gentle active movement.

Dislocations

Metacarpophalangeal Dislocations

These most frequently are caused by violent hyperextension. The head of the metacarpal is forced through the front of the capsule, while the base of the phalanx is dis-

Phalangeal Dislocations

These may occur in any direction, but usually the distal phalanx is displaced posteriorly. Reduction is achieved by traction and opposing pressure on the two phalanges. The joint should be splinted in flexion for 7-10 days.

Fig. 627A—Anatomy of the palmar aspect of the hand

The arterial circulation, in red, shows the communication between the radial and ulnar arteries to form the superficial palmar arch and its digital branches, and, in dotted lines, the formation of the deep palmar arch and its anastomoses.

The ulnar and median nerves, in yellow, supply the digital sensory branches to the ulnar $1\frac{1}{2}$ and radial $3\frac{1}{2}$ fingers, respectively.

The digital, ulnar, and radial synovial sheaths are also shown.

1, Flexor carpi ulnaris; 2, Flexor digitorum sublimis; 3, Flexor digitorum profundus; 4, Flexor pollicis longus; 5, Flexor carpi radialis.

Fig 627B.—Anatomy of the dorsal aspect of the hand

The dorsal arterial circulation, in red, is shown with the radial artery terminating by passing between the two heads of the first dorsal interosseous muscle

The digital sensory supply, in yellow, from the radial and ulnar nerves is shown Also the various extensor synovial sheaths in their relation to the dorsal carpal ligament

1, Abductor pollicis longus 2, Extensor pollicis brevis 3, Extensors carpi radialis longus and brevis 4, Extensor pollicis longus 5, Extensor digitorum communis. 6, Extensor minimi digiti 7, Extensor carpi ulnaris

After tendon severance, a jellylike substance extends from the cut ends into which the connective tissue grows for about $\frac{1}{2}$ " along each, and there is increased vascularity and swelling. *During the first week* a fusiform enlargement develops, which increases throughout the second week. If the tendon is confined within a thecal tunnel during this period, the swelling may result in ischemic necrosis and eventual dense adhesions.

The tendon cells begin proliferation in the second week. There is little strength in the union until the third week, when the tendon fibers begin to bridge the gap.

Between the third and fourth week the healing mass begins to separate from the surrounding tissues, and the fusiform swelling contracts and increases in tensile strength. This is the stage and time when graduated function increases the speed of union as well as the re-establishment of the gliding mechanism.

Mechanism of Injury.—The tendons may be individually severed by the puncture wound of a sharp spicule of glass or metal. Several may be sectioned with associated injury to nerves, blood vessels, bones, and joints in machinery or by lacerations on knives, broken bottles, china, or through glass windows.

Diagnosis.—A most careful history and examination of the movements of the hand and individual tendon functions must be made. Concomitant injuries to digital or major nerves must be determined by attention to sensory and motor loss. X-rays should be taken to ascertain the extent of skeletal damage.

Any defect in the movements of the fingers should suggest a cut tendon, and this must be excluded when the wound is cleansed and sutured.

Principles of Treatment.—The treatment of cut tendons is determined by the environment in which the injury occurs. If near a center where adequate facilities exist, the case should be immediately referred. Tendon suture is not a procedure for the general practitioner. It is best, if specialist facilities are unavailable, to carry out a careful cleansing of the wound and skin suture and then refer the patient later for secondary tendon repair. This will produce much better results than if primary suture is attempted with inadequate technique.

The time factor is of the greatest importance. After 2-3 hours the development of complications is greatly increased. Antibiotics should supplement the most careful wound toilet, and sepsis should be avoided at all costs. *Tendon injuries are acute emergencies and should be so regarded from the moment when first seen by the medical profession.*

Antitetanic serum should be given as a routine. If previously immunized, a booster dose of toxoid can be prescribed.

Technique of Suture.—There are two methods of tendon suture to be considered:

1. The silk technique

2. The removable suture of stainless steel (Bunnell)

Both have their place and both require experience to obtain good results.

Principles Underlying Operative Treatment.—

1. The most delicate handling of the tissues is required.

2. If both flexor tendons are sectioned in "No Man's Land," i.e., between the distal palmar and distal digital creases, the sheath should be exposed in its length and removed except for retaining bands over the joints. The flexor sublimis should be routinely removed if cut proximal to its insertion and only the profundus sutured.

3. In secondary suture of the flexor tendons, removal of the sublimis and profundus and replacement with a tendon graft from the palmaris longus sutured in the palm to the profundus tendon and in the theca at the base of the distal phalanx give the best results.

4. Incisions for the fingers should be in the midlateral plane, never longitudinally over the volar surface.

5. In the palm, incisions should follow the flexion creases.

Principles Underlying Postoperative Therapy.—

1. Immobilization with minimal tension is required for 3 weeks for the flexor and 4 weeks for the extensor tendons.

2. Every effort must be made to avoid postoperative swelling of the hand by elevation and by evenly applied compression dressings, with avoidance of constricting bandages.

Fig 629—A, The silk technique B, Bunnell technique.

Fig 630—Lines of incision (After Bunnell)

3. The best physiotherapy is the voluntary movement of the fingers in warm soapy water. Lanoline is useful to soften hardened skin. Sponge rubber can be used for grasp exercises.

Results.—The results of tendon suture are greatly improved by attention to the above principles. When cut flexor tendons in the fingers have been properly repaired, the tip of the finger can be flexed to the distal palmar crease. This is also the result to be expected after tendon graft has been employed in place of secondary suture. Repair of the cut extensor gives, on the average, a much better functional result than that of the flexor tendon

space. The cause is usually a prick of the volar surface. Because of the fascial septa limiting swelling, tension rapidly develops with acute throbbing pain. This pain is

Fig. 631—Incision of felon

INFECTION OF THE HAND

The hand is subject to the same infective processes as are the corresponding tissues in other regions of the body. The hand, however, is especially prone to involvement because of its functional activities

Historical.—The work of Kanavel and his followers did much to improve our understanding of this subject. The knowledge of the tremendous morbidity resulting from hand infections, together with the better understanding of the value of prevention and accurate therapy, has done much to lessen the ravages heretofore so frequently seen. The rise of industrial medicine with doctors and nurses present in the large factories enables prophylactic treatment of minor injuries and rapid transfer of the major accidents to specialist facilities. Finally, the development of the antibiotics has given the profession powerful agents to minimize hand infections. The future control rests in prophylactic care at the time of injury and in the use of the chemotherapeutic agents at the earliest moment associated with the most accurate and conservative surgery of this most important part of the body. Already the influence of these principles is obvious to those who compare this problem in large hospitals today with the period prior to World War II.

Infection of the Fingers

Felon

This type of infection is peculiar to the hand and connotes a cellulitis of the pulp

Fig. 632—X-ray of felon with sequestration of terminal phalanx

especially severe if the hand is dependent and is relieved by elevation. If the tension is allowed to develop beyond a certain point, the circulation to the distal phalanx is occluded, with necrosis and subsequent osteomyelitis

Diagnosis.—The diagnosis is made on the history of rapidly increasing pain, localized to the pulp space. The tense swelling of the area is noted on palpation. The point of injury may or may not be visible.

Therapy.—Elevation and immediate antibiotic therapy will clear the early cases. If seen late, an incision on the side sectioning the septa should be performed.

Paronychia

This is defined as an infection around the nail. The bacteria enter through a crack on the thickened cuticle of the manual worker or through a hangnail in the office employee. In hospitals, this infection was frequent in nurses when the nail brushes were not sterilized. One of the common causes today is the injury during manicure with nail file or clipper.

Fig 633—Drainage of paronychia and subungual abscess.

The process begins superficially as a subcuticular infection at the side of the nail. This forms a localized bead of pus, which evacuates itself or is easily evacuated. The infection may spread under the nail at the side and develop into a *subungual abscess*, lifting the nail from its bed. This is especially severe if the spread is to the base of the nail which is raised from its matrix. The skin overlying the nail base is raised, swollen, and reddish or bluish in color. The infection may spread completely around the nail, the so-called "run-around."

Diagnosis.—The clinical appearance at the different stages makes the diagnosis. Transillumination will show the pus beneath the nail as an opaque area.

Treatment.—Bathing the finger in hot water will soften the skin and accelerate localization and evacuation. When pus is present a small incision without anesthetic frequently suffices.

When the spread has occurred under the base of the nail, the nail should be transected at the lanula and the proximal portion avulsed under general or regional anesthesia. Local and systemic antibiotics will rapidly clear the infection.

Web Infection

One of the three triangular web spaces of the fingers may be infected by a prick, cut, or crack in the overlying dermis. The infection usually localizes, forming a pocket of pus, which tends to point dorsally. The process sometimes extends into the hand and involves the middle or thenar space.

Diagnosis.—The reddened swollen area, causing the adjoining fingers to spread, together with the spreading of the swelling onto the dorsum of the fingers is characteristic.

Treatment.—The hand should be elevated, and when the patient is ambulatory the hand can be secured in a sling. Hot bathing gives relief of pain. Systemic antibiotics are administered routinely. Incision will be required when the pus is localized.

Fascial Space Infections

Surgical Anatomy.—Three palmar and two dorsal fascial spaces should be considered.

- Palmar:** Middle palmar space
- Thenar space
- Hypothenar space
- Dorsal:** Subcutaneous
- Subaponeurotic

Palmar Spaces

The palmar fascia forms a dense roof overlying the deep structures of the palm consisting of the flexor tendons, the branches of the median and ulnar nerves, and the vessels. The floor is formed by the metacarpals, with the fascia overlying the interossei. From the ulnar border of the palmar fascia, a septum passes to be attached to the 5th metacarpal and separates the *hypothenar space* muscles

from the middle palmar space. On the radial side, a membranous septum passes to the 3rd metacarpal, forming the lateral boundary of the middle palmar space, which is thus separated from the thenar space. This latter consists of the area on the volar surface of the adductor pollicis and contains the tendons to the index and pollex together with the thenar musculature.

The importance of these fascial planes rests in the fact that they determine the passage taken by pus in its extension.

Dorsal Spaces

The dorsal subcutaneous space is found superficial to the dense layer of fascia and aponeurosis joining the extensor tendons. Deep to this plane is the subaponeurotic space. Pus contained in the deep space usually points at the periphery of the aponeurotic layer but may point directly dorsally in a collar-stud type of abscess.

Paths of Infection.—The middle and thenar spaces are those of the greatest surgical importance. Infection in the middle palmar space arises from direct puncture or lacerated wounds or from extension of deep infection of the long and ring fingers. Suppurative tenosynovitis of these two fingers or web infection may afford the source of infection by extension proximally.

The thenar space is involved by extension from deep infections of the index and volar aspects of the thumb.

The dorsal subaponeurotic space may be involved directly by puncture or lacerated wounds or secondarily by extension from the volar infections. Lymphatic drainage of the fingers extends to the dorsum and may carry the bacteria to the dorsal subcutaneous or subaponeurotic spaces.

Clinical Picture.—In severe infections the general reaction to infection will be present with raised temperature, pulse rate, and malaise.

Local signs give evidence of the infected space and vary with the extent and intensity of the inflammation.

Infection of the middle palmar space results in a swollen, brawny induration of the palm; the fingers are flexed and often the wrist also. Attempts to extend the fingers are resisted because of pain. Tenderness is localized over the middle of the palm. The site of the entrance of the bacteria may be seen. Because of the lymphatic drainage to the dorsum there is considerable swelling of this area as well.

Infection of the thenar space presents greater swelling due to the absence of the resistance of the palmar fascia. The tension

Fig 634—Fascial spaces

The middle palmar space thus exists deep to the flexor tendons and extends distally along the areolar spaces around the lumbrical muscles to the three web spaces. Proximally it extends through the carpal tunnel into the forearm deep to the flexor tendons.

The thenar space extends distally along the lumbrical canal to the radial side of the index finger.

is minimized by the abducted position of the thumb. The swelling is marked on both the palmar and dorsal surfaces

Infections of the dorsal spaces present a reddened and convex surface. The appearance is similar in the swollen dorsum seen in extension of edema from the palmar infections. The differential diagnosis is important and is made by a study of the path of infection and by the presence of fluctuation.

Treatment.—

Prophylactic.—Fascial space infections are best prevented by appropriate care of initial injuries and by the earliest possible use of antibiotics when infection has developed.

Suppurative Tenosynovitis

Infection of the synovial sheaths of the flexor tendons prior to the use of antibiotics was a most crippling disease. Few patients indeed preserved the mobility of the fingers and hand. Today the cases are less frequently seen and when the patients are treated by prompt incision and local and systemic antibiotics, functional restoration can frequently be expected.

Surgical Anatomy.—The flexor tendons of the thumb and fingers are surrounded by a synovial sheath. In the case of the thumb and little finger, this sheath extends from its in-

Fig 635—Synovial sheaths

Curative.—The hand should be carefully wrapped in bulky dressings which also afford splinting in the functional position of the hand and wrist. The part should be elevated. If the infection is severe, with general manifestation, the patient is best treated in bed. Massive antibiotic therapy should be given. When the process is localized and pus is present, surgical drainage is carried out. Local antibiotics may be instilled. A culture of the pus and a study of its antibiotic sensitivity are important.

section proximally into the radial and ulnar bursae surrounding the flexor pollicis longus and the flexor sublimis and profundus tendons, respectively. The synovial covering on the tendons of the index, middle, and ring fingers extends from the insertions to the distal palmar crease.

The radial and ulnar bursae lie close together in the carpal tunnel deep to the annular ligament. Communication exists here in the majority of cases. The sheaths extend proxi-

mally for a short distance above the annular ligament, projecting into the forearm fascial space.

The course of extension of the infective process can thus be readily seen. If the infection occurs on the thumb or little finger, involving the synovial sheath, extension will occur to the radial or ulnar bursa or finally both, with possible rupture into the forearm fascial space.

On the index finger, extension proximally will be into the thenar space, and on the long and ring fingers, into the middle palmar space.

Paths of Infection.—The synovial tendon sheath is usually involved from a puncture wound or laceration in the flexion creases on the digits. This may be a microscopic or macroscopic wound.

Clinical Picture.—The symptoms and signs of suppurative tenosynovitis are more marked than those of fascial space infections.

Toxic absorption is rapid, and the patient looks and feels ill with raised temperature (102° - 104° F.) and rapid pulse.

Locally there is exquisite tenderness localized to the digital sheath or to the ulnar and radial bursae, where extension has occurred. The finger is flexed and swollen when a single sheath is involved, or the whole hand is flexed and swollen when the ulnar bursa is involved. Attempts to extend the fingers give rise to intense pain.

Treatment.—

Prophylactic.—Immediate care should be given to puncture wounds. In medical personnel this is important in needle or scalpel pricks on septic cases. Careful sucking out of the blood and washing to encourage bleeding, followed by soaking in alcohol, is desirable.

Antibiotics should be given at the earliest sign of infection.

Curative.—Bed rest is indicated when infection has developed, and the part should be splinted and elevated. Systemic antibiotics should be forced.

The tendon sheath is best opened under tourniquet and general anesthesia, when the diagnosis is established. Local antibiotics should be instilled through a fine catheter.

When one digital sheath alone is involved and is seen late, amputation must be consid-

ered, with the exception of cases involving the thumb. This is especially true if involvement of bone or joint is present.

Lymphangitis

Lymphangitis is the most fulminating infection found in the hand. From a small prick a streptococcus or staphylococcus strain may enter the lymphatic system and rapidly spread proximally along the lymphatic channels.

The red streaks up the inflamed lymphatics are readily seen, and this renders diagnosis easy.

Treatment.—When first suspected, the patient should be treated in bed. In severe infections, general therapy directed to maintain the fluid balance is important. Today, with antibiotics, this dread process can rapidly be brought under control. Systemic antibiotics are forced. The limb is elevated and splinted. Cooling lead and opium or hypertonic saline dressings may be applied to diminish pain.

Human Tooth Wounds

Human tooth wounds of the hand are serious injuries and result from bites or a blow by the fist on the teeth. The wounds usually involve the knuckle area and penetrate through the extensor tendons into the adjacent joints.

Bacteriology.—*Streptococcus*, *staphylococcus*, *Bacillus fusiformis*, and spirochetes of Vincent's angina, *E. coli*, proteus, and anaerobic streptococci.

Clinical Course.—Unless treated early, the process runs a rapidly progressive course, with the development of a foul-smelling wound from involvement of tendons, joint, and subaponeurotic planes.

Treatment.—These wounds should be most seriously considered as the organisms are acclimated to human tissues. Surgical débridement is required with careful cleansing with saline, peroxide, and finally antibiotic instillation. The wounds are best left open and subjected later to secondary suture.

When seen later the path of infection should be opened and the wound treated with zinc peroxide. Cultures should be taken to indicate which antibiotic would be most efficacious.

DUPUYTREN'S CONTRACTURE

This consists of a contracture of the palmar fascia together with its digital extensions. It is named after Dupuytren, who described the pathology and clinical findings after dissecting a hand involved with this disease.

Clinical Picture.—The process is more common in the male sex and, contrary to common opinion, in the sedentary than in the manual worker. There is a hereditary tendency, and it is prone to occur in families subject to gout and cardiovascular degeneration. It has appeared acutely after coronary thrombosis. The patients are usually those with close-knit joints with a tendency to stiffness thereof even after minor trauma. The contracture develops in later years but has been seen in adolescence.

side of the hand. In the early stages there are signs of an active inflammatory process with round cell infiltration. The process runs a variable course, varying in its extent and intensity. Gradually, however, the fibrosis involves the skin, with loss of the fat lobules and skin glands by pressure atrophy. The extension to the fingers causes flexion of the proximal joints and increasing stiffness. The ring and other fingers are curled into the palm so that it is awkward for the patient when working and embarrassing when shaking hands.

Treatment.—Each case must be judged according to the stage of the disease and the actual disability to the individual patient.

When seen early the patient should be advised to avoid chronic trauma such as pressure

Fig 636—Dupuytren's contracture

The thickening first appears deep to the distal palmar crease and extends into the ring finger. The fingers involved in order of frequency are the ring finger, little finger, middle finger, index and thumb. The condition is frequently bilateral. There is an associated tendency to contracture in the plantar fascia and also in the fascia between the corpus spongiosum and corpora cavernosa of the penis.

Pathology.—The process begins as a fibroblastic proliferation in the palmar fascia deep to the distal palmar crease and on the ulnar

or strain to the involved tissues, for although trauma probably does not initiate the process, it appears to aggravate it. The use of a chamois glove for work or sports is helpful.

Operative therapy should be considered before the skin becomes too involved and the finger joints stiffened. If seen early, complete excision of the palmar fascia and its extensions through incisions in the palmar creases is best. If the skin is grossly involved, it must be removed and replaced by a split-thickness skin graft. When marked flexion and stiffness are present in the ring or 5th finger, interfering

with work, amputation may be indicated. The use of multiple subcutaneous fasciotomies does not give good results but may be employed as a preliminary to radical excision in severe cases.

GANGLIA

Ganglia are cystic swellings which are found in many parts of the body arising from joint capsules, ligaments, and tendon sheaths. They are especially common on the hands and feet.

Pathology.—Various theories exist as to their nature. Some believe them to be of neoplastic origin with the formation of the cystic contents by secretion of the connective tissue cells. Others hold that they develop because of connective tissue irritation in an area of mechanical derangement where ligament or tendon sheath plays over a bony prominence. Ganglia frequently communicate with joints, but few are due to herniation of the synovial lining.

Treatment.—Many ganglia around the wrist disappear spontaneously if a wrist support is employed. This is especially true of those over the dorsal aspect of the lunate bone.

The ganglia can be evacuated by direct blow or needling. The best method to secure a cure is by careful excision.

EPIDERMIOID CYSTS

Cystic swellings are found on the hands of manual workers and follow wounds with implantation of epithelial cells. Hence they are frequently called implantation dermoids. The cysts contain epithelial debris rich in cholesterol.

Treatment.—Excision.

TRIGGER FINGER

This is an interesting anomaly which results from a thickening in the proximal end of the

tendon sheath near the distal palmar crease or a swelling of the tendon mass where the sublimis divides to cross the flexor profundus. This results in a locking of the tendons at this point in the sheath, whereupon if the patient forcibly extends, the finger suddenly moves with a jerk. A similar derangement occurs in the thumb, and the site of disparity of tendon and theca is over the metacarpophalangeal joint.

Treatment.—Under local or general anesthesia the area is exposed through a transverse incision. The sheath is sectioned at the side for approximately 1", whereupon movements of the finger demonstrate that the mechanical derangement has been relieved.

TENDOVAGINITIS OF THE RADIAL STYLOID (DEQUERVAIN)

This condition should be correlated with trigger finger. It consists of a thickening of the tendon sheaths over the abductor pollicis longus and extensor pollicis brevis near the radial styloid. Mechanical irritation is probably the cause.

The patient complains of pain radiating from this area over the extensor aspect of the thumb and up the forearm. The lateral aspect of the lower end of the radius may show a tender fusiform swelling.

Treatment.—Under local anesthesia a transverse skin incision and longitudinal section of the tendon sheath are made. Immediate function is permitted. The results are excellent from this opening of the sheath.

CARPAL TUNNEL SYNDROME

In recent years a neuritis of the median nerve due to compression in the carpal tunnel has been described. The onset may be acute, subacute, or chronic and be caused by acute hemorrhage, acute or chronic tenosynovitis,

Fig 637.—Tuberculous tenosynovitis (compound palmar ganglion). This case began as a tuberculous osteomyelitis of the 5th finger, extending into the ulnar bursa, then involving the radial bursa, and later the carpal joints. Fluctuation could be obtained from above to the dorsal aspect of the carpus from the volar aspect of the 5th finger, with excision of the diseased synovia, followed by a series of antituberculous therapy was used of the radiocarpal, carpal, and carpometacarpal joints II and III. Antituberculous therapy was used in the preoperative and postoperative periods.

A, Anterior view. B, Lateral view. C, Melon seed bodies.

Fig 637.—For legend, see opposite page

ganglion formation, the presence of a displaced semilunar or scaphoid bone, or rheumatic changes in the soft tissue boundaries or contents.

Neuralgic pain and hypesthesia in the median distribution and motor weakness and atrophy of the thenar muscles will be noted on examination. The syndrome is immediately relieved by section of the transverse carpal ligament

TUBERCULOUS TENOSYNOVITIS

The synovial sheaths of the flexor and extensor tendons may be involved by tuberculosis. This is frequently secondary to disease elsewhere, such as in the lungs or lymphatic nodes. Characteristically the ulnar bursa is involved with the formation of a cystic swelling extending under the carpal ligaments in dumbbell-shaped arrangement. Fluctuation can be obtained from the forearm to the palmar portions, and the condition is referred to as a *compound palmar ganglion*. The cyst may contain fibrinous bodies of the melon seed or rice body variety.

Treatment.—The treatment is both general and local. The patient must be regarded as one with systemic tuberculosis, the treatment of the hand is incidental and should be timed for a period when the systemic reaction is minimal. Complete excision of the involved tissues is the ideal surgical therapy. Streptomycin, para-aminosalicylic acid, and isoniazid should be the associated chemotherapy.

Open Wounds and Soft Tissue Injuries of the Hand

Martin A. Entin, M.D

Soft tissues of the hand include all structures, with the exception of the bony skeleton, and thus represent most of the vital components. The most important of these are nerves, tendons, blood vessels, ligaments, and skin. Because the hand has evolved as an organ of perception and prehension, bulk and padding have been sacrificed to permit facile motion and ready perception. Moreover, a high degree of accuracy is required in the fitting of the various structures in order to permit agile and accurate synergistic movement of the various digits. These features make the hand vulnerable to injury from outside. Since great precision is required, even a small amount of distortion produces serious interference with function. Furthermore, open wounds of the hand pose one of the most frequent challenges in surgery and require immediate repair in order to avoid infection and scarring, which inevitably follow if such defects are not covered.

CLASSIFICATION OF INJURIES

Two classifications are available: one is based on the type of the mechanism of injury, the other is based on the potentiality of possible reconstruction. Both are valuable, because they complement each other and aid in quick assessment of a given injury regarding the most efficacious treatment and the probability of the ultimate function.

Types of Injury Based on the Mechanism of Trauma

Mechanical Injuries—These types of injuries are differentiated on the basis of the predominating character of the wound and consist of the following:

- | | |
|-------------------------|------------|
| 1 Incised (lacerations) | 4 Crushing |
| 2 Slicing | 5 Avulsing |
| 3 Amputating | 6 Mixed |

Thermal Injuries—

- 1 Burns (See Chapter 6)
 - 2 Frostbite (See Chapter 6)
- Electric Burns*—(See Chapter 6)

Only the mechanical injuries will be detailed here.

Incised Injuries (Lacerations).—These injuries are produced by either sharp or blunt objects and can be clean-cut (linear) or irregular (ragged).

Clean-cut Wounds.—These are usually closed directly. However, a linear wound that traverses the creases of a digit in the middle of the palmar aspect inevitably leads to contraction; consequently, such a wound should be primarily broken up by a series of Z-plastes in order to minimize the contractile force of the straight-line scar.

Irregular or Ragged Wounds.—These wounds may be converted into tidy ones by excision, provided closure without tension is possible.

Because of the proximity of the important structures to the surface, a linear wound is likely to sever tendons or nerves. On the volar aspect of the fingers, one or both flexor tendons may be involved, and usually a secondary tendon graft is carried out for tendon injuries within the tendon sheath. However, severed tendons in the palm, on the volar aspect of the wrist, and on the extensor surface of the hand or forearm are usually repaired immediately.

Slicing Injuries.—These injuries are produced by sharp objects and can be clean-cut (by a knife) or irregular (power saw) and may be accompanied by loss of skin cover.

No Loss of Skin.—All severed structures should be repaired in a fresh wound, except for tendons severed in the area of the fingers between the distal crease of the palm and distal pulley of the profundus tendon (no man's land). Because primary sutures of tendons in this area are notoriously unsuccessful, secondary tendon graft is usually recommended.

Loss of Skin.—If no vital structures are exposed, a free split-thickness skin graft is applied to the defect. If important structures such as tendons, nerves, vessels and bare bones are exposed, the area is covered either by a local rotation flap or by a distant pedicle flap.

Fig 638—Incised wound of the wrist, complicated by severance of 7 extensor tendons.
A, Appearance of the incised wound on the dorsum of the right hand of a 30 year old male 2 hours after injury.

B, Immediate definitive repair was carried out and all tendons were sutured. Photograph shows the range of extension 4 months after injury.

C, Same as *B*, showing the range of flexion.

Fig 639—Incised injury, complicated by severance of flexor tendons.
A, Both flexor tendons were severed through a linear wound at the base of the right middle finger. Initial treatment consisted of suturing of laceration.

B, Definitive reconstruction of severed tendons was carried out 3 weeks after injury, using extensor tendon of the 2nd toe as a graft to the middle finger.

C, Flexion of middle finger 4 months after tendon graft.

Amputating Injuries.—This type of injury is produced either by sharp objects (e.g., knife, saw) or by blunt ones (e.g., press). There may be a loss of a portion of one or several digits, and the amputation may be transverse or oblique.

Finger-Tip Injuries and Partial Loss of Digits.—If the thumb and index finger are involved, every attempt should be made to preserve the remaining length of the digits by application of a skin graft if the bed is suitable, or by a flap from neighboring fingers, or by a flap from infraclavicular or pectoral areas. For the remaining fingers, direct closure with the aid of shortening of the bony stump is most practical. (See Fig. 641.)

Loss of the Whole Digit (Near Metacarpophalangeal joints).—If the entire thumb is lost, the disability of the hand is great, and some form of reconstruction of the thumb should be employed at a later date. Pollicization of the index finger is the best method of thumb reconstruction because it provides a movable digit with sensation that can oppose the remaining fingers.

If the index finger is lost, oblique amputation of the 2nd metacarpal is usually

recommended. This procedure is done primarily for cosmetic reasons and should be carried out in women.

Total loss of *other digits* does not require special procedures and is well handled by direct closure of the wound, although shifting of the little finger onto the stump of the amputated 4th metacarpal avoids scissoring and provides a better appearance.

Loss of All Fingers (Metacarpophalangeal Level).—This is a very disabling injury; some function can be salvaged by deepening the cleft between the remaining portion of the thumb and the 2nd metacarpal.

Total Loss of Hand.—This is not a salvageable injury, and reconstruction is not practical.

Crushing Injuries.—This type of injury is produced by a force of compression or rotation and occurs in rollers, wringers, presses, and falling heavy objects. Either of two types of crushing injuries may occur, *closed* or *open*. The force of compression may cause a tearing or shearing of various strata of tissues upon each other, so that although there may not be any open wound, the skin and the underlying tissue may, in fact, be detached from their blood supply. When seen early, such *closed*

Fig. 640.—Slicing injury of the volar aspect of the ring finger, complicated by flexion contracture.

A, Flexion contracture of the left ring finger in a 17-year-old boy photographed 4 months after slicing injury.

B, Flexion contracture was relieved by excision of scar tissue and application of a pedicle flap, restoring complete extension.

C, Same as B, showing normal flexion of all fingers.

Fig 611—Amputating injuries. Diagrammatic representation of the management of the various amputating injuries of the digits of the hand

A, Amputation of finger tip with nail bed intact can be closed directly by removing a wedge of bone and soft tissue of the pulp until the edges of the wound approximate.

B, Fingers amputated proximal to the nail bed, with the exception of index and thumb, are closed directly after shortening of the bone

(Continued on opposite page.)

injuries may show little evidence of the gravity of the damage; however, later, edema and hemorrhage develop throughout the tissues and along the fascial planes. These pools of blood and fluid, if left untreated, impose additional insult to already injured tissues, causing further ischemia and even necrosis.

In the *open type* of crushing injury, the force of compression produces actual bursting of skin and fascia, through which deeper tissues can herniate.

Winger injury is a common example of the crushing type. It is easy to be misled into complacency in seeing a patient with this injury immediately after the accident, because occasionally it takes some hours for the edema and hemorrhage to become evident.

A good policy in management of all closed crushing injuries is to admit the patient to hospital. The involved area is x-rayed to rule out fractures, cleansed with antiseptic solution, wrapped in compression dressing, and mounted on a splint. Subcutaneous or subfascial hematoma should be evacuated immediately and again in 12 hours if accumulation recurs. Injection of hyaluronidase subcutaneously into the most distal part, along with compression and elevation, tends to reduce tissue edema. Such management will often prevent needless loss of skin in cases where damage is not irrevocable. (See also Chapter 30.)

Avulsing Injuries.—This type of injury has some element of crushing but is complicated by a partial or complete loss of tissue. Roller

Fig. 642.—Amputating injury of the right thumb through the distal joint

A, Definitive repair was carried out immediately by covering the bony stump with a pectoral pedicle flap

B, Appearance of the right thumb 3 months after injury, showing preserved length and good pinching action compared with the normal, uninjured hand

(Legend continued from opposite page)

C, Finger injuries resulting in loss of parts proximal to the distal joint are closed by shortening of the bone and formation of a volar flap of skin, so that the suture line is on the dorsum of the finger

D, Every attempt should be made to preserve the length of index finger and thumb. Amputations of index finger or thumb through the distal phalanx with the nail bed intact are treated by application of free-skin graft

E and F, For injuries proximal to the distal phalanx, if the bed is not suitable for a skin graft, cross finger pedicle or pedicle from pectoral area provides suitable skin cover with the least discomfort to the patient

G, When the thumb is too small to be useful, reconstructing by using finger new web cre

H, When amputation is not possible, the length of thumb can be extended by transfer of skin flap and bone graft. A long period of time is required to attain sensation in such covers

D, Appearance of the hand 3 months after repair

and wringer injuries are common examples of this type, and in complete avulsions the separated skin could be replaced as a full-thickness graft by trimming away fat and other debris. If the avulsed skin is not suitable for reposition, a free skin graft from elsewhere is obtained.

Incompletely avulsed skin that has good blood supply should be replaced in its original position. However, if the skin has been crushed

If the bed from which the skin has been avulsed is not suitable to sustain even a thin graft (bare or fractured bone, open joints, bare tendons, and major nerves), a distant pedicle flap must be used. In a degloving injury involving a finger or the hand, the exposed part is buried into a pectoral or abdominal pocket.

The avulsing injury can be further subdivided into subgroups on the basis of whether

Fig 644—Open type of crushing injury

A, Photograph of the dorsal aspect of the left index finger showing the skin defect and comminuted fracture involving the interphalangeal joint

B, The bony lesion was treated by immediate immobilization with Kirschner wires and direct closure of the defect. Patient ultimately had good pinch and grasp in spite of ankylosis of the proximal interphalangeal joint

or, as frequently happens in flaps with a retrograde attachment, the blood supply is not adequate to sustain the avulsed skin, the flap should be detached and should either be used as a full-thickness graft or be replaced by a fresh split-thickness skin graft

one or both surfaces of the hand are involved. These are *dorsal*, *palmar*, and *dorsopalmar avulsions*. This subdivision is practical because it reflects the increasing severity of injury and thus serves as a guide to appropriate early treatment (see Fig 647).

FRACTURES OF THE UPPER EXTREMITY

Dorsal Avulsions—These are usually produced by roller and wringer injuries and frequently involve damage to tendons or to the joint ligaments. Definitive repair is frequently possible in the injury of this type.

Palmar Avulsions—A greater force is required to produce this type of injury because the palmar skin is tougher, thicker, and more intimately attached to the underlying structures. Usually only initial treatment is possible, and definitive repair should be delayed to some later date.

Dorsopalmar Avulsions—This injury is frequently associated with loss of entire digits, immediate definitive reconstruction is rarely possible in this type.

Mixed Types of Injury—Like the avulsing type of injuries, the mixed types fall into three subdivisions, based on the predominant localization of the injury. The dorsal injuries usually give better prognosis, whereas dorsopalmar injuries are frequently beyond repair.

Crushing-Avulsing Injuries—In addition to the compression factor inherent in the crushing type, in the crushing avulsions there is also a severance of important structures, the tissues are torn away from the sources of blood supply; the blood vessels themselves are crushed and torn and become thrombosed, the avulsed skin, mauled by the crushing-compression force, has an impaired blood supply and, consequently, a reduced capacity

Fig. 645—Crushing injury produced by a laundry wringer in a 68 year old female

Fig 648—Crushing-avulsing injury of the dorsum of the hand in a 5 year-old boy

A. Right hand showing the extent of avulsion of skin from the dorsal aspect of the thumb, index finger, and hand. The metacarpophalangeal joints were exposed, and extensor tendons of index and middle fingers were severed.

B. The avulsed skin was discarded, and immediate closure of the defects was carried out by a sliding flap from the second web to cover the metacarpophalangeal joint of the index finger and skin grafting of the remaining areas.

C. Definitive reconstruction was carried out 10 months after injury. Widening of the first web was achieved by infraclavicular pedicle flap.

D. Photograph shows the extent of abduction of the thumb after application of pedicle to first web.

E. Appearance of the hand 10 months after injury. Flexion and extension of all fingers normal.

for healing and regeneration and a lowered resistance to infection.

Crushing-Avulsing-Amputating Type of Injury.—This type of injury results from exposure to mutilating machines, such as milling, corn-picking machines, or gears of roller presses. Usually the damage is so overwhelming that only salvaging procedures can be carried out. The initial treatment usually consists of providing skin cover to the remaining parts of the hand. Definitive repair is designed for restoration of some form of pinching and grasping motion.

niques, better understanding of the kinetics of hand function, atraumatic handling of tissues, and specific antibiotics. Although late repair requires specialized training, thorough understanding of the general principles of reconstruction of the hand and skills in providing good skin cover must be acquired even by the uninitiated who plan to carry out surgical procedures on the hand. Otherwise, tissues valuable for later reconstruction would be discarded at the initial treatment or hands left open to granulate, thus jeopardizing the success of later treatment.

Fig. 619.—Crushing avulsing injury of the dorsopalmar type

A, The dorsal aspect of the right hand of a 1½-year-old boy one week after injury by a laundry wringer. The necrosis of the 2 distal phalanges of ring and little fingers is apparent.

B, Palmar aspect of the hand 2 weeks after injury. The flexor tendons as well as the skin have been destroyed, and denuded bones and joints are seen in the middle and index fingers.

C, In order to salvage this hand, abdominal pedicle flaps were applied to index and middle fingers. The skin graft was used to cover the defect of the palm of the hand. Photograph shows appearance of hand 3 months after injury.

Crushing Injuries, Complicated by Burns.—This type of injury is produced by mangles and heated rollers. The complicating features of thermal injury to the skin make this type of injury rather difficult to treat since a period of waiting has to intervene in order to determine the depth of damage.

Types of Injury Based Upon the Potentiality of Repair

Early definitive surgery has been made possible through the improved surgical tech-

Moreover, as was pointed out earlier, it is important to know the possibilities and potentialities of reconstruction of a given injury of the hand. First, in certain types of injuries, however mutilating, it may be possible to carry out immediate definitive treatment which will provide the patient with a useful hand through the primary operative procedure. Second, some very severe injuries can ultimately give a reasonably good function if judicious initial treatment, reconstituting the skeletal alignment and providing adequate

finger would require punch and leave to this hand

finger would require punch and leave to this hand

finger would require punch and leave to this hand

cover of good quality, is carried out. Finally, some tragically mutilated hands cannot be salvaged regardless of the number of procedures, and they should therefore not be subjected to useless surgery.

The following classification has been found useful:

Curable.—Complete restoration of function is possible by one surgical procedure. Most of the incised and slicing wounds and some of the dorsal avulsions fall into this category.

Reconstructible.—This group of injuries requires at least two operative procedures.

Initial treatment entails alignment of the hand in a position of function, possibly repair of severed nerves and covering of all wounds.

Definitive treatment, consisting of procedures aimed at restoration of lost functions, is carried out at a later date.

Salvable.—Milling machine injuries, corn-pickers' hands, severe electric burns, and amputations through the metacarpals are some of the examples of injuries of this type.

Initial treatment would consist of immediate cover if the injury is recent and cleansable. Pedicle flaps may be required to improve circulation in vital parts, as well as to provide cover.

Definitive reconstruction in one or more stages is carried out at a later date to provide some prehensile function.

Non-salvable.—In very severe mutilating injuries any surgical procedure other than amputation is useless. Milling machine injuries, traumatic amputation at the wrist, and some electric burns belong in this group.

PRINCIPLES OF MANAGEMENT

The management of seriously injured hands constitutes a battle between the surgeon and the obstacles that may interfere with good healing and restoration of function. These obstacles are lack of blood supply, threat of infection, replacement of specialized structures by nonspecific scar tissue, and inertia due to immobility.

A number of objectives must be attained for good management of injured hands

- 1 Proper first aid
- 2 Accurate assessment of injury
- 3 Selection of an over-all plan of treatment

4. Minimum number of procedures to attain the maximum of function

5 Correct operative principles

6 Intensive mobilization between operations

7. Definitive reconstruction, if impossible at initial operation

8 Rehabilitation to speed return to useful occupation

The final result of treatment of severely injured hands depend upon the successful achievement of these objectives, and they will now be considered in greater detail.

First Aid.—First aid is very important in the management of a severely injured hand. The most practical method of initial handling is to apply a clean towel with a bulky dressing, maintaining the hand in neutral position, followed by elevation to the level of the shoulder, either in a sling or resting on the chest. Such bulky dressing will serve the triple purpose of stopping the hemorrhage, preventing contamination, and providing support to the injured structures.

Examination of an Injured Hand.—This examination should be done with sterile precautions without undue contamination of the wound by probing or shifting of tissues and without digging for deeper structures. A great deal of information can be obtained by inspection: sensory loss can be assessed by rapid examination of uninjured parts such as finger tips which extend beyond the main dressing covering the wound. Guarded active motion of various parts by the patient helps to determine the extent of motor injury or the severance of tendons. One should not rely on the information supplied by the patient regarding the performance of these movements nor on his impression of perception or sensation.

Planning the Course of Management of the Injured Hand.—Surgery is a two-edged sword: on the one hand it helps to reconstitute deranged tissue and on the other hand it leaves a telltale scar. Several surgical procedures in the same region may leave a wake of cicatrix which almost negates all benefit. Therefore the number of surgical procedures should be minimized, and even the initial operation should form part of a definite plan.

Such a program is based upon the extent and nature of injury, the age and general condi-

tion of the patient, his occupation, time after injury, and the cooperation that can be evoked from the patient himself. The plan consists of the following:

1. Careful estimate of the functional potentialities of the injured hand

2. Initial operative treatment (if definitive restoration of function is not immediately possible)

3. Timing of the subsequent operative procedures, each following a period of active remobilization

4. Definitive repair to restore lost function or later reconstruction to give some useful function to the hand

The over-all purpose of such a plan is to serve as a guide to provide the hand with good sensation, stable parts, and painless motion.

Disadvantages of Too Many Operative Procedures.—It would be theoretically possible to restore any lost function of the hand given enough time and a sufficient number of operative procedures. However, this may not be practical because of the length of time required and because every surgical procedure produces a certain amount of scar tissue. The formation of such scars is cumulative and eventually detracts from what can be gained. For these reasons a minimum of surgical steps should be selected in order to achieve a practical degree of function.

Correct Operative Principles.—The immediate objective of any surgical procedure is the restoration of normal structure and function. This can be attained only through early healing with a minimal amount of scar and the least amount of injury. Closest adherence to the correct principles in operative techniques is required to obtain these aims.

1. Cleansing of severe wounds should be performed only in the operating theater. Adequate scrubbing of the areas around the wound is done first in order to avoid further contamination. Copious quantities of saline or Ringer's solution are preferred for irrigation of the wound. Removal of foreign bodies, debris, and nonviable tissue is done after draping of the area. Detached pieces of bone should not be discarded.

2. Aseptic and atraumatic surgery is carried out with gentle handling of tissues in an avascular field under a pneumatic tourniquet.

3. Meticulous débridement of all devitalized tissue should be done.

4. Stabilization of bony framework should be carried out, preferably by intramedullary pinning, because plaster casts may add further insult to injured tissues.

5. Severed nerves should be repaired immediately if not contraindicated.

6. Scar tissue must be minimized by avoiding edema, hemorrhage, infection, and open wounds.

7. Immediate cover of all wounds should be performed by direct closure, skin graft, or rotating, sliding, or distant flaps.

8. The hand should be placed in the position of function.

Management of Open Wounds Several Days Old.—Old open wounds are always infected. In addition, there is a variable degree of tissue edema and gaping of the wound edges. Such wounds are more difficult to cleanse than the fresh ones and the débridement has to be more extensive. Consequently, judicious preparation of such wounds before surgical intervention by frequent moist saline dressings, elevation, and compression of the limb, alternated with application of proteolytic enzymes (Varidase and the like), speeds preparation of old wounds. A culture should be obtained and specific antibiotics should be given systemically and, if suitable, applied topically.

Intensive Mobilization Between Operations.—Active mobilization after each operative procedure is extremely important for the attainment of maximum function of the hand. Every type of injury requires some degree of immobilization of the various parts of the limb. Restriction of motion leads to undesirable changes even in the uninjured parts: (1) the propulsion of tissue fluids is hampered; (2) the synovial fluid in the joints is reduced in quantity; (3) the collateral ligaments shorten from disuse; (4) the lubrication of the flexor tendons, especially within the sheath, is diminished. Prolonged immobilization leads to narrowing of the joints and produces difficulty in movement, due to stiffness, swelling of parts, and adhesion of tendons.

In injured areas these sequelae are superimposed over the processes of repair of disrupted

parts and may seriously interfere with restoration of motion. Consequently, it is imperative to evoke motion as early as possible in all intact parts proximal and distal to the area of injury.

Initial Versus Definitive Treatment.—The aim of treatment in all injuries of the hand is restoration of normal function and appearance. This can be accomplished in many types of wounds, but in severe injuries immediate restoration of normal function is not possible. However, it is imperative to carry out a number of procedures at the initial operation in order that subsequent reconstruction for restoration of function may be possible. Thus, in severe injuries, the management is divided into two phases

Initial Treatment.—The following procedures should be carried out at the initial treatment if it is not possible to restore normal function

1. All wounds must be closed and defects of skin covered.
2. Skeletal structures should be aligned in normal anatomic position
3. Disrupted nerves should be repaired, if practical.
4. The hand and arm should be placed in the position of function

The immediate aim, then, is early healing and early motion of all parts, followed by definitive treatment in order to restore normal function.

Definitive Treatment.—Definitive treatment is directed toward restoration of normal function and involves provision of a better cover, repair of tendons or tendon grafts, and repair of severed nerves. Occasionally, transposition of muscles may be required in order to provide motion to parts whose own original tendons and nerves could not be repaired.

When restoration of normal function is not possible, one must give to the hand perception and prehension, composed of pinch and grasp, for these constitute a minimum of usefulness of the hand, and without these reconstruction is not really practical.

Rehabilitation.—Earlier definitive surgery has been made possible through the improved techniques, gentle handling of tissues, specific

antibiotics, and early mobilization. However, the treatment of the injured hand is not really completed until the normal or useful function of the hand has been restored and the patient has returned to a productive occupation. The process of rehabilitation of the injured individual begins when the patient is first seen by the surgeon and involves a team, which includes the patient and, in addition, the surgeon, the social worker, the physiotherapist, the occupational therapist, and the employer.

The important phases in the rehabilitation program are as follows:

1. Reassurance to the patient by the surgeon, as early in the treatment as possible, that all efforts will be directed toward regaining useful function of the injured hand
2. Initial or primary repair of the injured hand
3. Intensive mobilization between operations
4. Definitive repair to restore full function or to provide the maximal useful function possible
5. Active exercises designed to provide muscle contraction and joint mobility, progressing to coordinating and purposeful synergistic action
6. Productive occupational and group activity
7. Return to original occupation
8. Selection and training for a new trade

The final outcome of any severe injury is affected by the age of the individual, duration of reconstruction, length of gaps between treatment, and the number of surgical procedures. However, in all long-term cases the surgeon and the other members of the team must continuously evoke an optimistic outlook in the patient, encourage attempts at early motion, and ignite a desire to get well quickly.

Fractures and Other Disorders of the Lower Extremity

H Fred Moseley, DM

PELVIS

The pelvic cage functions for the protection of the lower abdominal viscera and for the transmission of weight from the trunk to the inferior extremities "Within its borders are housed a portion of the urinary and intestinal systems and the female genitalia, through its foramina pass the great nerve trunks and blood vessels, while beneath its arches, passes all mankind, with few exceptions, the most notable Julius Caesar" (Howell).

Fractures of the pelvis are serious injuries and are frequently complicated by associated trauma to the urethra, bladder, and rectum. In this respect they are comparable to fractures of the skull and spine where involvement of the brain, cord, and meninges constitutes the major problem in therapy.

Mechanism of Injury.—Fractures of the pelvic ring are caused by lateral or anteroposterior compression. The accidents of travel in train, car, and plane account for some. Crushing beneath heavy weights or between cars account for others. Direct falls on the trochanteric area may fracture the acetabulum. Direct violence to different areas causes isolated fractures, e.g., the ilium. Indirect violence by muscular force produces avulsion fractures. Diastasis of the symphysis may occur during parturition or from hyperabduction of the thighs.

Classification.—

A Pelvic ring

- 1 Superior and/or inferior pubic ramus, unilateral or bilateral
- 2 Diastasis of symphysis pubis
- 3 Associated with 1 or 2, fracture through ilium or sacrum on same or opposite side or sacroiliac dislocation

B Acetabulum

- 1 Rim—with posterior or anterior dislocations of the hip
- 2 Floor—with varying degrees of central dislocation of the hip

C Isolated fractures

1 Avulsion

- a Anterior inferior spine by rectus femoris
- b Anterior superior spine by sartorius
- c Ischial epiphysis by hamstrings

- 2 Direct trauma—wing of ilium

D Sacrum and coccyx

Associated Injuries.—

A. Visceral

- 1 Urethra
- 2 Bladder, intraperitoneal or extraperitoneal rupture
- 3 Rectum

B Nervous —Injuries to lumbosacral plexus —S1,2 characterized by the clinical signs:

1. Toe drop
2. Loss of Achilles' reflex

Fig 651—Type fractures of the pelvis

Fig 652—Male patient, aged 28 years, was cleaning the interior of a large cement mixer when the switch was accidentally turned on. Wide diastasis of the symphysis pubis and upward dislocation of the left sacroiliac joint. Ruptured abdominal muscles produced a traumatic ventral hernia. No injury to bowel, bladder, or urethra.

Clinical Picture.—The patient presents the general picture of shock in severe crushing injuries. Visible deformity is not often present. There may be pain localized to the pelvis on attempting to bear weight, or the patient may localize the pain and tenderness to different parts of the pelvis when lateral or anteroposterior compression is applied. Retroperitoneal hemorrhage commonly results from pelvic fractures as from fractured vertebrae. It is indicated by fullness and tenderness in the lower abdomen. Ecchymosis may be visible over this area after a few days, and ileus is a frequent complication.

The diagnosis is accurately made and any displacements of the fragments noted on x-ray examination, which is essential.

Because of the possibility of visceral injury, the patient is asked whether he has passed urine and, if so, whether blood stained. If urine has not been passed, the patient is advised against doing so. The presence of blood at the urethral meatus or a perineal hematoma indicates urethral damage. Suprapubic tenderness or early abdominal rigidity suggests rupture of the bladder (see Chapter 31).

A rectal examination is necessary to ascertain injuries to this viscus, and by this route fractures of the rami may be palpated.

Treatment.

General.—If it is necessary to move the patient, this is best performed after binding the pelvis to prevent displacement. Therapy directed toward shock may be required. The patient is placed on a firm mattress supported by fracture boards except when diastasis of the symphysis pubis is present. In such cases, sagging of the unsupported mattress assists reduction of the displacement.

Visceral.—Catheterization should be carefully carried out. Failure to enter the bladder indicates rupture of the urethra. If the catheter enters the bladder but fails to drain urine, an intraperitoneal rupture must be suspected. The presence of a small quantity of blood-stained urine suggests extraperitoneal rupture and extravasation (see pp. 883-885 and Fig. 451). Lacerations of the rectal wall found on rectal examination or vesical injuries require laparotomy and repair when possible.

Local drainage, proximal colostomy and antibiotics are associated measures.

Fractures

Pelvic Ring

Fractures of the rami do not displace greatly and unite without residual disability after 3-4 weeks of bed rest.

Fractures of the anterior and posterior sections of the ring without displacement are best treated in bed for 4-6 weeks. A sling support often gives comfort to the patient.

Fractures of the anterior and posterior sections of the ring, with displacement, require treatment in a pelvic sling together with traction on the side of upward displacement of the innominate bone. This correction is best effected with skeletal traction through the lower end of the femur. Six to eight weeks are required for union in the reduced position.

In cases of disruption of the anterior and posterior segments of the ring, caused by anteroposterior compression, the innominate bone hinges outward on a posterior axis like a bivalve mollusc. This displacement is maintained, in the dorsal recumbent position, by the weight of the lower limb. Reduction is best carried out by placing the patient on his sound side on an orthopedic table, compressing the displaced innominate bone forward and medially, and applying a plaster spica to include the lower lumbar spine, the pelvis, and both thighs in moderate abduction to knee level (Watson-Jones). This method is also used for diastasis of the symphysis pubis. When upward displacement is present, downward traction is also required, and this skin or skeletal traction should be retained. Twelve weeks' immobilization is necessary.

Reduction of such displaced fractures is indicated when rupture of the bladder or urethra is present, in order to approximate the torn soft tissues as a preliminary to the urologic procedures of repair and drainage.

Acetabulum

Rim. This is usually part of the treatment of the primary dislocation of the hip. Crepitus may be noted at the time of manipulative reduction, or incomplete reduction or recurrent

dislocation may occur. When radiologic examination reveals a large posterosuperior fragment involving the weight-bearing surface or should recurrent dislocation ensue, operative exposure with internal fixation is indicated. The posterolateral (Gibson) approach affords the best access

Floor. In these cases the problem is how to avoid or minimize traumatic arthritis. When no displacement occurs, the treatment consists of gentle movements with avoidance of weight-bearing for 3-4 months. With central dislocation of the femoral head, clinical examination will disclose some shortening of the limb and

a fracture at the junction of the ilium and superior ramus of the pubis. This can be exposed through the iliofemoral (Smith-Petersen) approach, reduced, and internally fixated. Other types involving the junction of ilium and superior ramus of the ischium can be similarly treated by a posterior exposure

Improvement in the end results is being reported.

Weight-bearing should be avoided for 4-6 months and the progress followed for several years to note the development of aseptic necrosis of the femoral head and traumatic arthritis.

Fig 633.—Pelvic sling

lessened prominence of the trochanter, pressure over which will augment the discomfort, and there will be pain, crepitus, and restricted movement in rotation of the thigh. X-rays will indicate the position of the fracture line and the extent of the protrusion. Reduction is carried out at the earliest moment by strong traction on the abducted leg

Since the end results of such fracture-dislocations are invariably poor due to the mechanical arthritis resulting from incongruity of the acetabulum and frequently associated aseptic necrosis of the femoral head, primary operative reduction has been advocated. Elliott has pointed out that the common type presents

Isolated Fractures

In avulsion fractures rest for 3-4 weeks in the relaxed muscle position is indicated.

Sacrum and Coccyx

Avoidance of pressure and bed rest for 2-3 weeks are required. Fractures of the coccyx are rare, but ligamentous injuries are common and are prone to be followed by a painful neuralgia, i.e., traumatic coccydynia. This is best treated by avoidance of pressure on sitting by use of an air ring supplemented by local diathermy. Excision of the coccyx may be necessary in chronic cases

In all serious injuries of the pelvis, a firm canvas support should be provided when the patient becomes ambulatory. Ambulation on crutches is advisable before full weight-bearing is allowed. Any tendency to pain in the sacroiliac area merits, in addition, massage and diathermy treatments.

Late Complications of Pelvic Fractures.—The late complications are as follows:

1. Malunion with interference, in female patients, with the pelvic canal and parturition
2. Traumatic arthritis of the hip
3. Osteomyelitis following extravasation of urine
4. Sacroiliac pain
5. Traumatic urethral stricture
6. Coccydynia
7. Residual diastasis of the symphysis which results in little disability

THE HIP

The hip is a ball-and-socket joint formed by the articulation of the globular head of the femur in the acetabular fossa of the innominate bone.

The hip joint permits a greater range of mobility than any other joint in the body except the shoulder. At the same time this joint has remarkable stability due to the close fit of the femoral head into the acetabulum as well as to the support of the strongest capsular ligaments and the most powerful musculature of the body.

The hip joint is the most deeply situated of all joints. This increases the difficulty of diagnosis and, unfortunately, renders thorough operative exposure difficult.

The region of the hip is most easily localized by the prominence where the soft tissues overlie the greater trochanter. Anteriorly, the femoral head lies just below Poupert's ligament and lateral to the femoral vessels. The posterior aspect of the hip is bounded by the gluteal or buttock area.

Ligaments

The femoral head is attached at the fovea capitis to the acetabular notch and labrum by the ligamentum teres, which carries a vascular supply (foveolar artery) from the obturator

or medial femoral circumflex vessels to the head.

The capsule of the hip joint is especially strengthened by *Bigelow's ligament*, which extends as an inverted Y from the anterior inferior spine to insert along the full length of the intertrochanteric line. This is the strongest ligament in the body and is rarely ruptured even in dislocations of the joint.

When dislocation occurs, *Bigelow's ligament* acts as the pivot around which the head of the femur moves into the various characteristic positions to be described later. The ligament as a whole limits extension; its external band limits eversion.

The *pubofemoral ligament* extends from the pubic bone above the obturator foramen to the inner part of the intertrochanteric line. This ligament is made taut by abduction and serves to check this movement.

The *ischiofemoral ligament* passes from the tuber ischii to the upper part of the greater trochanter on its posterior aspect. This band arrests flexion and inversion.

Musculature

The superior and posterior aspects of the joint capsule are covered by a group of small external rotator muscles, i.e., the *piriformis*, *obturator internus* and *gemelli*, the *obturator externus* and *quadratus femoris*. Of these the *obturator internus* must be emphasized because of its great tensile strength and because dislocations of the hip posteriorly tend to displace either above or below this muscle into the gluteal or sciatic position, respectively.

This group of small muscles forms the bed on which the sciatic nerve and gluteal vessels lie. The close relation of this major nerve to the joint explains the frequency of its injury in posterior dislocations.

The *glutei minimus* and *medius* strengthen the joint superiorly and laterally.

The capsule on its anterior aspect is covered by the *iliopsoas* muscle passing to insert on the lesser trochanter. Between the capsule and this muscle lies the *psaos bursa*, which frequently communicates with the joint cavity.

More laterally the *rectus femoris* arising from the anterior inferior spine covers the anterior capsule. The most important anterior

Plate 67.—Blood Supply to Upper End of Femur and Hip.

relations of the hip are the femoral vessels and nerves coursing over the anterior surface of the iliopsoas in the floor of Scarpa's triangle.

Extending superficially over the posterior and lateral aspects of the hip is a layer of aponeurosis and muscle corresponding to the deltoid at the shoulder and made up of the gluteus maximus and tensor fasciae femoris. Between the gluteus maximus and great trochanter is a large bursa which is characteristically involved by tuberculosis and also by calcified deposits similar to those found in relation to the subacromial bursa.

Arteries and Nerves

Blood is supplied to the hip by the gluteal and obturator arteries and by the circumflex femoral branches of the profunda femoris. The obturator and circumflex arteries nourish the acetabulum, head, neck, and trochanteric areas of the femur, whereas perforating branches of the profunda supply the femoral shaft.

The blood supply to the head and neck of the femur is of especial importance. The work of Wolcott, Tucker, and Trueta and co-workers indicates that the main blood supply is through the posterolateral and posteroinferior retinacular vessels. The anterior retinacular vessels are of lesser importance. The nutrient artery sends branches which anastomose with the retinacular group. Some differences in opinion exist as to the significance of the foveolar vessels. Plate 67, based on Wolcott's observations, indicates that after the age of 14 years anastomoses occur between the foveolar and retinacular vessels in 80% of patients.

The above information should be correlated with the fact that in fractures of the neck of the femur impaction occurs superiorly and posteriorly, preserving the posterior retinacular vessels. It is in the displaced subcapital fractures that the retinacular vessels are most likely to be disrupted or thrombosed, leading to aseptic necrosis of the femoral head.

The muscles of the hip joint are dependent on the lumbosacral plexus for innervation. The iliofemoral group of muscles may be divided into an anterior group (iliopsoas), innervated by the lumbar plexus, and a posterior group (the gluteals, piriformis, and tensor

fasciae latae), supplied by the sacral plexus. The ischio-pubo-femoral muscles, or the lateral rotators of the thigh, also derive their nerve supply from the lumbosacral plexus. In the thigh, muscles are supplied by branches of the femoral, obturator, and sciatic nerves. It is interesting to note that the hip itself is little affected when the sciatic nerve is damaged by a dislocation. Nerve fibers to the muscles of the hip are given off at a high level so that damage from dislocation is shown only distal to the femoral condyles.

Functions of the Hip

The chief functions of the hip joint are (1) transmission of the superincumbent weight of the body to the lower limb and (2) movement at this line of junction.

Because of the transmission of weight, the hip joint is specialized for *stability*. This is in contradistinction to the shoulder joint, which is organized for *mobility*. This emphasis on stability is seen in the depth of the cup of the acetabulum as compared with the shallow fossa of the glenoid. Furthermore, the articular head of the femur protrudes from the femoral neck and is at some distance from the trochanters to which the small muscles are attached, whereas in the shoulder the articular head and tuberosities are continuous.

The weight of the body is transmitted through the roof of the acetabulum to the head of the femur and thence down the neck to the shaft of this bone. In the neck of the femur, the lamellae are architecturally arranged so as to give the greatest possible strength. This arrangement begins to develop in childhood with the beginning of weight-bearing. It attains its greatest development at the most active period of life and is reduced by bone absorption occurring during senescence.

A strong development of compact bone, called the *calcar femorale*, extends along the lower surface of the neck, from which radiating lamellae extend to the upper surface of the neck and head. As age advances, the loss of this bony structure, originally differentiated by stress and strain, constitutes the chief predisposing factor to fractures of the femoral neck.

It is possible that endocrine factors play a considerable role in this process of osteoporosis.

Movements.—The movements of the femur on the pelvis at the hip joint correspond to those of the humerus on the scapula at the glenohumeral joint but are much more restricted in range. These movements are as follows.

1. *Flexion*, which is finally limited by the thigh impinging on the abdomen

2. *Extension*, which permits the thigh to bend behind the coronal plane of the body. This movement is limited by the tension of Bigelow's ligament to about 10-15 degrees. Extension is best tested with the patient prone and the knee flexed at 90 degrees. The diseased hip with a fixed flexion deformity, when tested for this movement, reveals complete absence of extension

3. *Abduction*, which permits separation of the lower limbs. This is limited by tension of the pubofemoral ligaments and impingement of soft tissues between the greater trochanter and acetabular rim. Abduction is best tested with the hips flexed and feet together when the comparison with the normal side is readily made. Most hips when diseased have a fixed deformity of flexion and adduction. Hence, limitation of abduction is an important diagnostic sign

4. *Adduction*, by which the lower limb is brought across the sagittal plane of the body. When fixed adduction is present on both sides, as is seen in spastic paraplegia (Little's disease), the characteristic scissors gait is present

5. *Circumduction*, which is a composite of each of the preceding movements

These five movements constitute all those that occur at the hip joint. However, a complete understanding of the clinical examination and lesions of this joint would be lacking if we did not also consider the rhythm of movements in this region corresponding to the *claviculo-scapulo-humeral* rhythm of the shoulder mechanism. We refer to this as the *pelvic rhythm*, since the pelvis as a unit is moving synchronously with the lumbar articulations and the upper end of the femur, as well as with the knee, ankle, and foot joint mechanisms. This concept is of the greatest importance, since the simple act of bending

forward to touch the floor involves not only the question of hip flexion but also flexion throughout the vertebral column, especially at the lumbosacral joint. Furthermore, any stiffness or restriction of motion in one of these areas is compensated for by increased motion at the other joint mechanisms. An appreciation of these points should greatly assist the student in his examination of the hip joint disordered by injury or disease.

Examination of the Hip

The student may gain his first impression as the patient limps around the ward with or without the support of cane or crutches. The appearance of the older patient of sthenic habitus with excess weight immediately suggests degenerative arthritis in the weight-bearing joints. A careful history will throw light on the duration of symptoms and the disorder to be suspected. Clinical examination is best carried out on an examining table having a rigid surface

Inspection.—Observation of the patient lying supine will reveal the presence of any deformity, such as *eversion* of the whole limb, which is so characteristic of degenerative disease of the hip as well as of fractures of the femoral neck. The inability to flatten the thigh and leg on the couch will suggest the presence of a *flexion deformity*. *Muscular atrophy* affecting the thigh and buttock indicates organic disease of some duration

Before taking measurements for any *disference in limb length*, it is well to level the pelvis by seeing that the line joining the anterior superior spines is at right angles to the midline of the body. Such measurement is made from the anterior superior spine to the internal malleolus on each side.

Palpation.—Manual examination in the region of the anterior aspect of the femoral head and greater trochanter may disclose localized tenderness.

At this point, the level of the tip of the greater trochanter is compared on each side by palpation and also by drawing *Nélaton's line* upon the skin. This line from the anterior superior spine to the ischial tuberosity just crosses the tip of the greater trochanter when the leg is flat on the table.

Upward displacement of the trochanteric area is present in degenerative arthritis of the hip, in gluteal dislocations, in fractures of the femoral neck with displacement, and in non-union of such fractures with characteristic upward riding of the femur.

The shape of Bryant's triangle is another indication of how much, if any, the trochanter has been displaced. This triangle is formed by (1) Nélaton's line just described, (2) a line from the anterior superior spine dropped perpendicular to the examining table, and (3) a line from the tip of the greater trochanter perpendicular to the line just mentioned (or parallel to the examining table). The relative displacement of the trochanter can be determined by a comparison of the shape of this triangle on the affected side with that on the normal side.

Test of Mobility.—It is best first to examine the hip for fixed deformity. With the patient supine, the thigh on the normal side is flexed completely upon the abdomen. With the examiner's hand flat under the patient's lumbar spine, the normal lordotic curve is found to be obliterated. The thigh with knee flexed is held firmly against the abdomen, and the patient is instructed to hold his limb manually in this position.

If fixed flexion of the unsound hip is present, the thigh on the affected side must flex during this manipulation. With the knee on the involved side in extension and the pelvis fixed by the patient as just described, the unsound limb is lowered toward the couch until it reaches a stable position. In this position the angle of the thigh with the table indicates the fixed flexion deformity at the hip. This has been called the *Thomas test* for the demonstration of this deformity.

To determine fixed adduction, the pelvis is first leveled by movements of the lower limbs until the anterior superior spines are aligned perpendicular to the midline. The angle made by the affected limb with the midline of the body when the leg is carried outward as far as it will go will indicate the extent of the adduction deformity. This deformity can also be brought out by testing the range of abduction when the hips are flexed and the feet side by side. As the knees are then pushed apart, any limitation of abduction (indicating

a fixed adduction deformity) on the side of the lesion will be apparent.

By manually moving the sound limb through its various ranges of motion and by repeating this on the side of derangement, a good idea of all the limitations of motion can be obtained.

Radiologic Examination.—X-ray examination should include a view of the whole pelvis, with both hips on one film, taken in the anteroposterior plane. Special oblique and lateral views are also indicated in cases of fracture of the femoral neck or acetabular roof.

The localization of the femoral head in the normal, compared with the displaced, position is determined by x-ray examination (see Fig. 659). Nélaton's line also is invaluable in such determinations.

Examination of the lumbar spine should be included in cases of degenerative disease of the hip, since advanced disease in this vertebral area will contraindicate an arthrodesis for the hip disease. Fusion would throw too great a strain on the lumbar spine and cause pain more intolerable than that from the hip itself.

FRACTURES OF THE NECK OF THE FEMUR

These acute injuries constitute the chief group of emergencies involving the hip. Although these fractures can occur at any age, they are characteristically found in the elderly patient. They occur with increasing frequency from the 6th decade onward.

Fracture of the femoral neck, formerly called the "unsolved fracture," suddenly converts the the ambulatory aged person into a completely bedridden one. If this situation is not corrected, physical and mental deterioration usually ensue. Before the general use of internal fixation, this accident was a frequent cause of death.

Types of Fracture

Subcapital Fracture.—The thin old lady who has passed her biblical span of life is the typical case in whom subcapital fracture occurs. The predisposing factor is senile osteoporosis involving the lamellae of the femoral neck with loss of the *calcar femorale*. A sudden slip on a scatter rug, polished floor, or

linoleum and the bone gives way, the patient sinking to the floor. There the doctor finds her, unable to rise because of pain, with tenderness localized over the femoral head and the limb everted in the typical deformity.

Transcervical and Intertrochanteric Fractures.—These also occur in the aged but are often found in the younger age groups. The mechanism of fracture may be similar to that just described. However, it is frequently due to a forcible fall on the trochanteric area.

On palpation, the trochanter will be found less prominent and more highly placed in the displaced fractures of the subcapital, transcervical, and intertrochanteric types. Nélaton's line and Bryant's triangle can be outlined to confirm this point. In the displaced subcapital fracture, shortening will vary from $\frac{1}{2}$ -1"; in the extracapsular types, the shortening is still greater.

Movements of the limb are painful. The complete inability of the patient to raise the

Fig 634—This illustration stresses the angle formed by the line of fracture to the horizontal. Pauwels showed that in the abduction type of fracture, this angle was under 30 degrees, and it can be seen that the two opposing forces, (a) body weight and (b) muscle pull, tend to impact the fracture. However, when the angle is greater than 30 degrees, there is an increasing shearing force at the site of fracture caused by the opposing forces of body weight and muscle pull. The greater this shearing force, the greater the necessity for internal fixation and the more secure must be the means of internal fixation.

The extent of the eversion deformity is usually greater in the intertrochanteric cases because of the loss of attachment of Bigelow's ligament to the trochanter and shaft fragment.

Diagnosis.—Fractures of the femoral neck will be suspected from the history and the age of the patient. Eversion of the limb is characteristic, but it may be absent or replaced by inversion in an occasional case.

The patient complains of pain in the area of the psoas insertion and adductor region, which sometimes confuses the examiner.

leg from the couch and the localization of pain to the groin on attempts to do this are important points in diagnosis. Acute tenderness can be elicited over the anterior aspect of the femoral neck.

If gradual traction is made, the limb can be readily brought down to its proper length and crepitus elicited by gentle rotation.

All these findings may be absent in IMPACTED fractures at the different locations in the femoral neck. The student must remember that a patient may actually walk with such a fracture, and if x-rays of the hip are

not taken in such cases, unfortunate medico-legal complications may ensue.

The clinician must, therefore, arrange for x-ray examination of all patients suspected of having fracture of the hip

Emergency Treatment.—The patient should be transported in a Thomas splint arranged with fixed traction. Morphine 15 mg should be given to relieve pain

Definitive Treatment.—The introduction by Smith-Petersen of the three-flanged nail has been one of the great contributions to fracture treatment. Although other methods of

tality of about 25%. With the proper use of the Smith-Petersen nail, union can be expected in 75-80% of cases, with a mortality of about 10%. These statistics are only rough; however, they are sufficiently accurate to give an indication of what can be expected from this method of treatment.

The displaced fracture of the subcapital type will not unite without reduction and internal fixation. Reduction consists of traction on the flexed thigh while adducted and externally rotated. This is followed by movement into internal rotation, abduction, and extension. If

Fig. 656—A. Aseptic necrosis of femoral head following subcapital fracture treated by Smith-Petersen nail. Note track from which the nail has been removed.

B. Result following excision of head and replacement by Moore prosthesis

internal fixation, such as multiple pins, lag screws, bolts, etc., have been successfully employed, most surgeons rely on the Smith-Petersen nail

Prior to the introduction of this method, the use of a Whitman plaster cast secured union in possibly 40% of cases, with a mor-

tal reduction is stable and the heel of the affected extremity is placed in the surgeon's palm, the limb will not immediately fall into the externally rotated position. This reduction has been called *Leadbetter's maneuver* and the test for stability, *Leadbetter's test*. The author has not found this test of great practical value

In these cases, therefore, the nail should be expertly inserted at the earliest possible moment. Most surgeons will agree that little is gained by delay, and elderly patients withstand the operation well.

Recently, in the *adduction type* of subcapital fracture in the patient 70 years or older, the use of a prosthesis has been tried because this type of fracture in the aged has been the one with the greatest percentage of nonunion and the longest periods of immobilization. With the prosthesis, the patient is immobilized for only 3 weeks and thereafter is encouraged to move about freely. Because of the short life expectancy in such cases, this method holds considerable promise.

The *impacted* subcapital fracture will unite without internal fixation but should be protected by a plaster spica in the more vigorous patients. In the elderly patient, it is probably safer to insert a nail to obviate the possibility of a later displacement.

Transcervical and intertrochanteric fractures do not present the same difficulties in securing union. However, in the hands of specialists, the use of internal fixation causes the least inconvenience to the patient and makes the problem of nursing much easier. An intertrochanteric fracture requires a side plate in addition to the nail, since the tongue of bone extending from the shaft is usually not sufficiently strong to support the nail.

In the younger group of patients presenting these fractures, reduction and fixation may be secured by the use of skeletal traction arranged through a Kirschner wire in the lower end of the femur. This must be maintained in place for 8-12 weeks. Sometimes a sufficient degree of union has occurred in 6-8 weeks to warrant change to a plaster spica, which will permit the further bed confinement to be carried out at home. Progress of union and position should be followed in these cases by repeated x-ray examination.

Postoperative Therapy.—If the fracture is well nailed, patients with the above types are allowed to move freely in bed. Six to eight weeks of such confinement is conservative in this type of treatment. If necessary, the patient may be allowed to sit up in bed immediately or be lifted into a chair. This will obviate

pressure sores from prolonged rest in one position.

Ambulation on crutches is determined by the patient's capacity. Often this is too dangerous to consider.

Union occurs in 3 months in the intertrochanteric, 4 months in the transcervical, and 4-6 months in the subcapital fractures. However, these are only arbitrary time factors, and union is best judged by radiologic examination. Internal fixation is only a means of maintaining position. Time and the healing process are the essentials for union.

The nail need not be removed except when complications develop.

Physiotherapy in the Elderly Patient.—In all elderly patients with fractures of the femoral neck, the physiotherapist can supervise deep-breathing exercises from the beginning to prevent postoperative pulmonary complications.

With the use of a beam over the bed, the patient can be taught to assist her own movements when a bedpan or change of sheets is required. With a well-nailed fracture, the therapist can encourage movements of both lower limbs from the beginning to obviate venous stasis and the possibility of phlebotrombosis and pulmonary embolism. The patient can be assisted to sit on the side of the bed and even to a chair shortly after operation. Once the stitches are out and the wound is soundly healed, a walker can be used. The exact timing of graduated activity will be determined by many factors, including the general capacity of the individual, the type of fracture, and the security of the fixation obtained by the nail and plate.

Complications.—

General.—A fractured hip in the senile patient is still an all-too-frequent cause of death. The initial shock, together with the early development of pulmonary, cardiovascular, or renal complications, is often too much for the frail body to bear. Before the internal fixation technique was employed, pressure sores from long confinement to bed were additional factors disposing the patient to deterioration.

Local.—The most important local complication of the fracture is *nonunion*. This is most common in the subcapital type but is rare

in the transcervical and intertrochanteric types, which unite well although sometimes with a *varus deformity*. The nonunion is often associated with *avascular necrosis* of the capital fragment. The initial displacement ruptures the cervical ligaments that carry the main vascular supply, leaving only an inadequate supply via the ligamentum teres. The density of the head is increased as seen on x-ray, and if weight-bearing is permitted, collapse of the head and traumatic arthritis ensue.

In those cases in which the nail does not secure effectual fixation of the fragments, a shearing force is exerted at the fracture line and *absorption of the femoral neck results*. This is a frequent cause of nonunion and of extrusion or fracture of the nail.

Treatment of nonunion of femoral neck fractures depends upon the viability of the head, absorption of the neck, and general factors such as the patient's age, general health, and expectation of life. In the senile patient, if treatment because of pain is necessary, the most promising results are from the use of a prosthesis. In the younger patient with a viable head, bone-grafting operations or a McMurray osteotomy can be used. An arthrodesis can be performed if immobilization for 3-4 months can be justified.

Complications of Nailing.—

Extrusion of the Nail.—In cases where aseptic necrosis of the head develops or where a shearing force at the line of fracture occurs, the nail moves in the line of least resistance. In cases where the head of the nail is fixed to the shaft, the nail will penetrate into the joint. Where it is not so fixed, the nail will be extruded. This is due to the fact that the more vascular bone of the shaft area atrophies more rapidly around the nail and therefore permits the extrusion. Treatment depends upon the individual case and follows the principles outlined under nonunion.

Penetration of the Nail.—In cases where the nail has been hammered too far and has penetrated the joint, withdrawal is required because of the painful arthritis which develops.

Fracture of the Nail.—Occasionally the nail may break and require removal or replacement.

End Results.—A follow-up of 242 cases admitted to the Royal Victoria Hospital for the years 1951-1955, inclusive, has recently been completed by Dr. I. Bitenc.

TYPES AND INCIDENCE

Femoral Neck (108)

Impacted subcapital (valgus)	11.1%
Vertical (Pauwel's III)	11.1%
Transverse subcapital	51.8%
Transverse mid-cervical	24.1%
Basocervical	19%

Trochanteric (134)

Intertrochanteric	25.2%
Intertrochanteric (comminuted)	51.8%
Intertrochanteric and subtrochanteric	7.8%
Subcervical (reversed intertrochanteric)	2.6%
Subtrochanteric	8.6%
Greater trochanter	4.0%

99 patients showed signs of advanced cardiovascular disease

18 patients were diabetics

18 patients had other fractures

8 patients presented pathologic fractures

Highest incidence of neck fractures occurred in 8th decade—female:male = 4:1

Highest incidence of trochanteric types occurred in 9th decade—female:male = 2:1

Treatment.—Patients moribund on admission were afforded palliative treatment. Whenever possible, internal fixation was employed at the earliest moment. Displaced neck fractures in patients of advanced age were sometimes treated by prosthesis or excision of the head. Impacted subcapital fractures were treated both conservatively and by internal fixation.

Results.—In displaced femoral neck fractures treated by internal fixation, union occurred in 87.7%, avascular necrosis in 14.2%, operative mortality being 3.1%; mortality in cases treated conservatively was considerably higher.

In 12 impacted subcapital fractures, all united; one developed avascular necrosis.

In the trochanteric types, all united whether treated conservatively or by internal fixation. The mortality was halved by the operative treatment, 8.1% and 16.2%, respectively.

The mortality in those operated upon was least when the operation was performed within 48 hours and increased considerably thereafter.

SEPARATION OF UPPER FEMORAL EPIPHYSIS (ADOLESCENT COXA VARA)

This disorder occurs typically in the Fröhlich type of endocrine obesity in the age range 10-16 years. It will be remembered that the capital epiphysis fuses with the neck about the 19th year.

The condition may occur acutely, but more often it develops gradually. The displacement is frequently bilateral. However, in such cases one hip is usually involved before the other.

The onset may follow different degrees of trauma but may also occur spontaneously. The soft tissues are intact, but the capital epiphysis rotates backward as the neck and shaft fragments rotate forward.

Diagnosis.—The patient is usually an overweight adolescent 10-16 years of age, with a history of pain in the groin. Whether acute or chronic in nature, the earliest possible radiologic examination is required. Anteroposterior views are not adequate to demonstrate early

Fig 657—Male patient aged 16 years. Case of delayed puberty with early slipping of left femoral epiphysis.

A, Anteroposterior view of both hips. Little abnormality to be seen.

B, Oblique view of abducted hips. Note inferior displacement of head on left side.

C and D, Similar views showing result after Smith-Petersen nailing.

displacement, lateral views are essential to show the projection backward of the capital epiphysis.

Treatment.—A period of observation in the orthopedic ward is essential. If early diagnosis by x-ray is secured, internal fixation by a Smith-Petersen nail is the accepted treatment. Should displacement be marked, reduction by gentle, graduated traction is preferred to forcible manipulation, which may interfere with the circulation to the head and lead to aseptic necrosis.

With reduction secured by traction, plaster immobilization or preferably internal fixation may be used. Supervision must be continued until epiphyseal union has occurred. X-ray films of the opposite limb should be made repeatedly because the process is frequently bilateral. The avoidance of weight-bearing during the period of waiting for synostosis of the epiphyseal plate is one of the essentials of treatment.

TRAUMATIC DISLOCATION OF THE HIP

These major accidents are much less commonly seen than are fractures. A dislocation usually occurs in the younger age group. It is rare in the elderly patient because in such a person the bone is relatively weaker than the joint capsule. Dislocations occur chiefly in automobile accidents. The so-called "dash-board dislocation" is the one seen most commonly.

Types of Dislocation.—It is a surprising fact that little can be added to the descriptions of dislocation given by Hippocrates. However, we are greatly indebted to Bigelow, whose studies on this subject published in 1869 remain the classic today. This surgeon emphasized the significance of the inverted Y-shaped ligament of the hip, which bears his name, and demonstrated that most dislocations leave this ligament intact to act as a controlling band around which the head rotates. Bigelow referred to the dislocations with this ligament intact as *regular* in type and those with rupture of this ligament as *irregular*.

The regular dislocations occurring clinically are characterized by the same position of the femoral head in relation to the acetabulum and the same corresponding deformity of the

limb that occurs when the identical dislocations are produced on the cadaver. Bigelow also showed that reduction can best be secured by circumducting the limb around this ligamentous pivot. With the ligament of Bigelow ruptured, however, the head assumes irregular positions determined by the direction and intensity of the force that has been applied.

Bigelow's studies were continued by Allis, who published his observations in 1896.

For our purposes, it will be sufficient to recognize four positions of the regular dislocations:

1. Posterosuperior—also called dorsal or gluteal
2. Posteroinferior—below the tendon of the obturator internus—also called sciatic
3. Anterosuperior or pubic
4. Anteroinferior or obturator

Variations of these will be found when one or both branches of Bigelow's ligament have been ruptured. Most classifications describe the fracture of the acetabular floor, with varying degrees of pelvic protrusion of the femoral head, as *central dislocation of the hip*.

Diagnosis.—The diagnosis will be made on the history of a serious accident, often with multiple injuries, of which the hip is one site. The patient will usually be of the younger age group and almost certainly younger than 50 years of age.

In the *dashboard dislocation*, caused by direct force against the knee with the thigh flexed and adducted, the femoral head is driven out into the gluteal position. This type is frequently associated with a fracture of the acetabular roof in its weight-bearing portion. This is a most serious complication, and if the fragment is large, internal fixation of this weight-bearing surface in perfect position will be required to prevent traumatic arthritis after closed reduction of the dislocation has been performed.

The femoral head will be palpated in its dorsal position; the limb will be shortened and adducted. X-ray examination will confirm the diagnosis and position.

Other types of dislocation can be diagnosed by the abnormal position of the head, the abnormal shortening or lengthening of the limb, and the x-ray appearances.

D, Central

Treatment.—The first important point is to secure complete relaxation of muscle spasm by spinal or general anesthesia, which should be induced at the earliest possible moment after the accident.

DORSAL DISLOCATIONS.—These are the more frequent. Three methods of reduction are available:

Gravity Method.—The patient is placed face downward on a firm surface, with the affected thigh and leg flexed at right angles over the side of the table. Gentle, graduated traction to the thigh will usually secure reduction.

Method of Allis.—The patient is placed supine on a firm mattress on the floor.

1. Flex the thigh to 60-70 degrees and the knee to 90-100 degrees. The pelvis is fixed by an assistant. Gentle traction is applied to the thigh.

2. Apply force sufficient to lift the head into the acetabulum. If resistance is felt, give gentle rotation inward, then outward, and follow this by lifting upward.

3. The limb is now extended while the lifting force is maintained. Reduction usually occurs at this point.

Circumduction Method of Bigelow.—The position of the patient and limb is as for the method of Allis.

1. The limb is first flexed, rotated inward, and adducted, which relaxes the taut capsular ligaments.

2. While maintaining traction, the limb is abducted, rotated outward, and extended in one continuous movement.

All surgeons agree that, with complete muscle relaxation, reduction can be secured with single or repeated manipulations without the use of excessive force, which would further damage the capsule, vascular supply to the head, and the sciatic nerve.

ANTERIOR DISLOCATIONS.—These can be reduced by the methods of Allis or Bigelow as follows:

Method of Allis.—Abduct the slightly flexed thigh while the assistant steadies the femoral head with his fingers. While applying gradually increasing traction to the thigh, adduct the limb as the assistant pushes the head laterally into the socket.

Method of Bigelow.—The limb is first flexed to a moderate degree, and with gentle

traction the abducted and externally rotated limb is successively adducted, internally rotated, and finally extended.

Postreduction Treatment.—The affected hip should be placed in balanced traction for 3-4 weeks. After this time the patient should be instructed in the re-education of hip movements. Because of the high incidence (as high as 50%) of aseptic necrosis and traumatic arthritis, differences of opinion exist as to the optimal time at which weight-bearing should be permitted. However, it would appear that graduated return to full weight-bearing can be permitted after 4 weeks, since little evidence exists that prolonged rest minimizes these sequelae.

Complications.—Sciatic nerve paralysis found at the initial examination is a serious complication. This and fracture of a major part of the acetabular roof afford the chief indications for operative exploration.

Late cases presenting traumatic arthritis with marked symptoms will require relief by arthrodesis or arthroplasty, depending on the indications in the particular case.

CONGENITAL DISLOCATION OF THE HIP

The hip is the joint which most frequently presents a congenital dislocation. It occurs more frequently in girls than in boys, in the ratio of 4:1, and 1 out of every 3 cases presents a bilateral lesion. There is a geographic and racial incidence noted. This congenital anomaly is especially common in northern Italy, where Putti made extensive studies and contributions on this subject. It is rare among Negroes. There appears to be a hereditary tendency to this defect.

The term congenital dislocation includes the various degrees of displacement of the head from its normal position and thus includes subluxations.

Pathologic Anatomy.—The acetabulum is shallower, and its roof presents a greater obliquity, than normal. There is a postero-superior defect of the acetabular rim. In many cases the acetabulum is obliterated by fibrous tissue and capsular adhesions. There is a false joint above the acetabulum on the dorsum ilii.

The upper end of the femur is also abnormal. The epiphysis of the head, which

appears in infants 6-8 months of age, is hypoplastic and sometimes undergoes an osteochondritic process. In the early stages before ambulation the head is more laterally placed from the floor of the acetabulum than normal. In the later stages the shape of the head is altered from pressure changes, being flattened on its medial and posterior aspects. The normal anteversion of the neck is increased and the neck points almost directly forward. There is an increased neck shaft angle. In patients 20-30 years of age the x-ray appearances of degenerative arthritis, characterized by cystic areas and osteophytic changes, are noted in the head.

Fig. 659—The method for localization of the head of the femur in relation to the acetabulum. *AB* = horizontal line through points of fusion in the acetabula. *CD* and *EF* = perpendicular lines drawn from the superior rims of the acetabular roofs. Normally, the head lies inferior to the horizontal line and medial to the vertical line. In congenital dislocation, as shown on the right side, the head lies superior to the horizontal line and lateral to the vertical line. The head, in such cases, is usually late in development.

The capsular changes have been studied at operation, autopsy, and lately by arthrography. In some cases the capsule is drawn out in hourglass arrangement, and part of the capsule intervenes between the head and the false socket on the ilium. The hourglass constriction permits the passage of the ligamentum teres carrying part of the blood supply to the head. This constriction is a barrier to manipulative replacement, as it intervenes between the head and acetabular socket on closed reduction.

It is generally agreed that before ambulation has occurred the head is usually capable of being replaced in the acetabulum by abduction of the limbs. With the passage of time, adaptive structural changes occur which make anatomic position more difficult to obtain and retain. Early diagnosis will depend on the careful examination of the hip joints of all infants with radiologic studies, if deformity or limitation of movements is found. If the preluxation state is demonstrated, treatment can be initiated at the earliest moment.

Clinical Features.—

Preambulant Period.—The radiologic examination is the key to the discovery of the preluxation. At birth an increased obliquity of the acetabular roof can be noted. At 1 month any increased lateral displacement of the upper and inner corner of the femoral metaphysis may be seen and after 6-8 months the delay in the development of the upper femoral epiphysis or its smaller size can be demonstrated.

Ambulant Period.—As soon as the child begins to walk, a definite limp will develop. In the unilateral case there will be lurch to the affected side. There is a *positive Trendelenburg test* which means that when the child stands on the affected leg and raises the other from the ground, the pelvis will lower on the normal side because of the lack of the stabilizing influence of the gluteal muscle group. Clinical examination will also disclose an increased number of folds on the medial and posterior aspects of the thigh. Palpation will reveal the absence of the head in Scarpa's triangle, and the femoral pulsation will be more difficult to obtain for this reason. The head may be palpated in the gluteal area. Movements of the hip are altered, and there is limitation of abduction and internal rotation with increased adduction and external rotation. It may be possible to telescope the upper end of the femur. There is a greater than normal prominence of the great trochanter, and measurements will reveal that the trochanter rides above Nelaton's line, joining the anterior superior spine to the ischial tuberosity.

X-ray at this period will show that the head is more superiorly and laterally placed than normal and the line of Shenton is broken.

Fig. 660—A. Congenital dislocation on right side. Shenton's line, which is shown in its normal arrangement on the left side, is broken on the right side.

B. The same case after reduction by traction. Note the increased slope of the acetabular roof and the delay in the development of the femoral head on the right side.

In the bilateral case the child walks with a waddle. There is greatly increased lumbar lordosis and protuberant abdomen, giving the appearance that the trunk is falling forward on the posteriorly displaced hip mechanisms. There is a bilateral positive Trendelenburg test.

Diagnosis.—The work of Putti has shown that by public education this anomaly can be diagnosed in the early months of life if the possibility is suspected and radiographic studies are made. Any infant presenting limited abduction of the flexed hip merits investigation and supervision. After ambulation has begun the diagnosis is made on the characteristic limp and clinical features mentioned above.

Treatment.—If this congenital anomaly is diagnosed in the preluxation period, positioning the limbs in abduction and internal rotation on various type of mattresses, cushions, or braces for periods of 6 months or more can effect a cure. This is only of value within the first 6 months of life.

After this time, the treatment consists of gentle reduction of the dislocated head by traction followed by positioning the limbs in full internal rotation until stability is secured, which averages 9 months. This position is maintained by plaster fixation which is changed at 3 monthly intervals. As soon as the reduction is stable, dynamic splinting in abduction may be employed instead of plaster fixation (Denis Browne).

In those cases that relapse or where reduction was impossible, the displacement may be corrected by open operation. This group often shows a high degree of anteversion of the neck which requires correction by external rotation osteotomy.

When the patient presents later with such dislocations a variety of reconstructive procedures may be employed.

OSTEOARTHRITIS OF THE HIP (DEGENERATIVE ARTHRITIS, MALUM COXAE SENILIS)

Apart from the traumatic disorders of the hips, which are chiefly the fractures and dislocations previously discussed, osteoarthritis of this joint is the lesion most frequently encountered. This is a progressive and disabling

disease, more common in the male than in the female patient, which occurs with increasing frequency from the 5th decade onward. There is a constitutional predisposition to this form of arthritis. It tends to occur in families of the sthenic habitus with a tendency to be overweight. Their joints are of the close-knit, stable variety, and the summation of minor and major traumas, the wear and tear of daily use, and the effects of aging all play their part in its development.

Macroscopic Joint Changes.—Articular cartilage changes are most marked on the non-weight-bearing area of the head, where the cartilage becomes fibrillated, softened, and finally desquamated, exposing the bare bone. The bone becomes dense, polished, and eburnated.

At the periphery of the head, excess production of *enchondral* bone takes place to give the exostoses, or lipping, which accounts for the term *hypertrophic* frequently applied to this type of arthritis. These changes in the articular cartilage are reflected in the x-ray, which discloses a diminution of the joint space and lipping on the head and acetabular rim.

The *subchondral bone* undergoes atrophy and cyst formation. The bone marrow shows fibrosis and fatty infiltration. The *synovial membrane* presents signs of chronic inflammatory change. Villous processes develop. The synovial fluid loses its mucous character and becomes more serous in consistency. The *joint capsule* and *ligaments* lose their elasticity and become thickened from fibrous tissue proliferation. The *surrounding muscles* undergo contractures and the hip assumes a position of deformity characterized by flexion, adduction, and external rotation. The muscles of the buttock and thigh atrophy from disuse.

Clinical Picture.—A middle-aged man walking with a limp and supported by a cane is the typical picture. Usually of the sthenic habitus and carrying excess weight, he comes for medical aid, complaining of increasing pain and stiffness in his hip and thigh. At first the pain is an ache on overuse and is noted only at the end of the day. It is relieved by rest from weight-bearing. In time the ache becomes more constant and reaches a stage where *night pain*

interferes with sleep and relief is difficult to secure. The pain is aggravated by dampness, cold, overuse, and postural strain. Often it increases with work in the patient who is of the laboring class.

As the pain and stiffness increase, the typical deformity of eversion, flexion, and adduction develops. This places a strain on the lumbar spine, and an associated low backache is a frequent complaint.

In some cases, there is a history of adolescent coxa vara, Perthes' disease, or a previous dislocation or fracture, which has contributed to premature wearing out of the joint. Initially, the disease is unilateral, but in time the opposite hip is also affected

Fig. 661—Osteoarthritis of the hip. Note loss of joint space, sclerosis of the head and acetabular roof in the weight bearing portions, as well as cystic changes in these areas and osteophytic formations at the acetabular rim.

Radiologic Examination.—The early x-ray picture is one of diminution of the joint space, with cystic areas of decreased density in the subchondral zones of the weight-bearing areas of the head and acetabular roof. Lipping on the periphery of the head and acetabular rim is seen in later stages, and the joint space

appears to be absent. However, bony ankylosis practically never occurs.

Diagnosis.—The diagnosis is readily made on the history of gradually increasing pain and stiffness, with the clinical picture of a limp, in a patient presenting deformity characterized by flexion, adduction, and eversion of the leg. The radiologic examination will conclude the evidence. The condition may be unilateral or bilateral and varies in the degree of involvement.

The presence of Heberden's nodes on the terminal finger joints and symptoms and signs in other joints will indicate the systemic process present in these cases.

There is little difficulty in differentiation from involvement of the hips in Marie-Strümpell spondylitis, in which clinical examination will disclose a rigid poker spine with limited chest expansion. X-rays will show the typical sacroiliac sclerosis.

Conservative Treatment.—Conservative measures will be devoted to the relief of pain. The general health should be improved by conservative weight reduction and limitation of activity within the capacity of the joint as indicated by the presence of pain. During an acute phase, relief from weight-bearing by bed rest associated with massage, diathermy, and gentle repetitive hip exercises is beneficial. When the patient is ambulatory, a raised heel of the shoe or the support of crutches or a cane will give relief. Analgesics can be employed as required.

Operative Treatment.—In cases where pain becomes a burden and especially in the younger patient who is prevented from doing his work by the hip disease, operative intervention should be carried out.

In the unilateral case where the patient's health will permit immobilization in plaster casts for 3-4 months, a combined intra-articular and extra-articular arthrodesis will secure a painless hip that will give good service. The hip is best fused in 20-30-degree flexion, 5-degree abduction, and slight external rotation.

However, arthrodesis must not be considered in the case presenting marked pain in the low back with x-ray changes of advanced lumbar arthritis. In these cases and in

those presenting a bilateral lesion, an arthroplasty to retain a partial range of movement is indicated. The various methods of securing this need not be detailed here. Suffice it to say that at the present time, the replacement prosthesis for the femoral head made of stainless steel or Vitallium is replacing the mold arthroplasty, which has been in vogue for the past 14 or 15 years. This method appears to give the best results to date in this difficult field of reconstructive surgery.

Other operative procedures, such as denervation of the hip or capsulectomy and its variants carried out for the relief of pain, all have their advocates. Similarly, the McMurray osteotomy to correct the flexion-adduction deformity has been successfully used in certain cases. There is a multiplicity of procedures, all selected by different workers for individual cases, which time will finally evaluate.

OTHER DISORDERS OF THE HIP

Space will not permit the discussion of the many other clinical lesions that involve this joint. The student must remember the *congenital subluxations and dislocations* presenting at birth and in the early years of life. All suspected cases must be subjected to careful and repeated clinical and radiologic examinations.

From the ages of 5-10 years, the possibility of *Perthes' disease (osteochondrosis of the upper epiphysis)* will be suggested in the youngster with aching pain and a limp. At a later age, around puberty, a *slipped epiphysis* requiring detailed lateral views of the hip may be encountered.

At all ages the possibility of *tuberculous or pyogenic arthritis* must be considered, but again these disorders are most frequently found in the younger age groups.

Atrophic arthritis commonly involves the hips as part of the polyarthritis of rheumatoid arthritis or ankylosing spondylitis. This type generally occurs in the female during the 3rd, 4th, and 5th decades.

Inflammation may involve the *psaos bursa*, giving rise to a swelling which presents in the groin and requires differentiation from *hemis*, saphenous varicosity, and *psaos abscess*. The *ischial bursa* may enlarge and give a fluctuant

swelling under the lower border of *gluteus maximus*.

Finally, the *trochanteric bursa* may be chronically involved by tuberculosis or by secondary spread from amorphous calcium deposits in the *gluteus medius tendon*. This latter gives rise to an acutely painful swelling over the trochanter. X-ray examination will usually show the calcium. The course is similar to that found in the subacromial bursitis so common in the shoulder.

Fig. 662—X-ray of Legg-Perthes' disease. Note the fragmented appearance of the head and widening of the metaphyseal region. The revascularization and creeping substitution of the head require about 3 years.

SHAFT OF THE FEMUR

The shaft of the femur is the longest and strongest bony structure in the body. It has normally an anterior and lateral bowing. Fractures result from great violence and are difficult to reduce. Following reduction they are difficult to maintain in position because of

the powerful muscle forces acting upon them. There is a tendency for fixation of the quadriceps to the healing area with consequent limitation of function. This is one of the factors causing the stiff knee, which is the chief disability after such injuries.

Mechanism.—Direct violence of great severity is the usual cause. Indirect violence giving a torsion force and resulting spiral fracture accounts for a smaller number.

The displacements taken up initially depend on the direction of the causative forces, but the powerful muscles gradually pull the fragments into positions of characteristic deformity.

In *supracondylar fractures*, the lower fragment is angulated backward by the *gastrocnemius*. Reduction must therefore be carried out with these muscles relaxed by flexion of the knee and a counterforce applied to maintain the corrected position.

Clinical Picture.—The patient is in great pain and may be in shock, with associated injuries to other structures. Deformity is sometimes marked, and the fracture area is surrounded by a large hematoma. Local tenderness and crepitus will be found. The patient is moved with great difficulty, X-rays reveal the type of fracture and displacements.

Fig. 663.—Influence of muscle pull on fractures of the femur.

Fractures of the upper end present flexion, abduction, and external rotation of the upper fragment and adduction of the shaft produced by the adductor magnus. Because of this, reduction and fixation are best arranged in flexion and wide abduction of the whole limb.

Fractures of the shaft proper in its middle half present adduction of the lower in relation to the upper fragment, with overriding caused by the spasm of the hamstrings and quadriceps. External bowing is produced frequently in these cases. Traction must therefore be maintained in moderate abduction.

Treatment.

Emergency Treatment.—The limb should be splinted before moving the patient. A Thomas splint with fixed traction or a plaster spica is the ideal method and is used if the patient is to be transported long distances. If such facilities are not available, fixation of the two limbs together and both fixed to a rigid support can be used. Morphine should be given to alleviate pain.

Definitive Treatment.—Various methods of treatment may be considered for shaft fractures occurring in adults, and the choice will

depend on the judgment of the surgeon in charge:

1. Traction and countertraction
2. Manipulation and plaster spica
3. Open operation and internal fixation
4. External-skeletal fixation

Principles Underlying Therapy.—Reduction in adults should be anatomic if possible in cases of femoral fractures, but this is sometimes impossible to achieve. Angulation must be avoided at all costs and the proper length of the limb maintained. Furthermore, alignment of the bones should be such as to avoid abnormal stresses and strains on the adjacent joints above and below. In children, because of the overgrowth in length of the shaft due

to the hyperemia of repair, an average of 1 cm. overlap is the ideal. In children under 4 years, Bryant's suspension or a plaster spica is the usual method, whereas skin traction is the routine after this age.

If reduction in adults can be secured by conservative measures such as skin or skeletal traction, these methods should be employed. Sometimes interposed tissue or injuries to other bones or the patient's general state may demand the use of open operative reduction and internal fixation to facilitate aftercare.

If traction is employed in adults, skeletal is preferable to skin traction. The Kirschner wire or Steinmann pin may be placed through the lower end of femur or upper end of tibia.

Fig. 664—Balanced traction for fractured femur. Inset shows site for insertion of Kirschner wire or Steinmann pin. A in femur; B in tibia.

Either site has its advantages and disadvantages.

The pin should not be placed through the lower end of the femur in the vicinity of the fracture hematoma which may thus become infected.

The pin should be driven from the inner to the outer side to avoid injury to the femoral vessels in Hunter's canal and should not penetrate the suprapatellar pouch since spreading infection may cause inflammation and obliteration of this pouch, with resulting stiffness of the knee.

It is technically easier to put the pin through the upper end of the tibia at the level of the tibial tubercle. When skeletal traction is applied at this site, however, the force is transmitted through the knee joint of which the ligaments may be stretched. This danger is avoided if the extension is not maintained too long or with too great force.

When the patient is under anesthesia the pin is introduced and traction is set up. The

fracture is manipulated to the correct length of limb and correct position, and traction and countertraction are instituted. Approximately one-seventh the body weight is adequate for purposes of extension, but x-ray follow-up gives the best indication of the amount to use in the individual case.

It is wise to avoid pin traction from one site of longer duration than 4-6 weeks.

When x-rays show satisfactory position and good callus formation (8-12 weeks), traction is replaced by a plaster spica or Thomas caliper. The Thomas caliper may be used subsequently as a support when the patient becomes ambulatory on crutches.

When it is decided that open operation is indicated, the anterolateral approach is employed and a 6- to 8-screw plate is applied, with the screws transfixing both cortices.

A Thomas caliper may be used as a splint in the postoperative period preferably to a plaster spica. Ambulation should not be permitted until 6-8 weeks have passed, and pro-

utilized for children under 3 years of age of the traction and, on the average, must be clear of by . . . is necessary to prevent excessive the bed.

Fig 666—Fracture of the femoral shaft, treated by intramedullary nail

tective splinting is necessary for approximately 4-6 months

The subtrochanteric fracture presents a special problem and is probably best treated by open operation and internal fixation with a Smith-Petersen nail and long side plate. Intramedullary nailing may be considered for this type of case.

Recently, for fractures of the upper two thirds of the shaft, intramedullary fixation by Kuntscher nail has been employed. The site of fracture is exposed by the anterolateral or posterolateral approach, the guide wire inserted retrograde through the distal end of the proximal fragment and through the trochanteric area followed by the insertion of the nail over the guide wire. The nail is driven down through the fracture line into the distal fragment under direct vision. This method enables immediate movements of the knee and ambulation on crutches in 10-14 days. It has become the treatment of choice in selected cases when expert care is available.

Some cases in the young show spiral fractures with little displacement. These can be treated by plaster spica fixation.

External skeletal fixation may also find a place in selected cases.

It is most important in fractures of the femur to maintain the activity of the quadriceps muscle and at the earliest moment obtain the return of knee function.

Transverse fractures of the femur usually unite more slowly than the spiral fractures. In the adult, the time loss from work averages 8-12 months.

Complication.—The chief complication is stiffness of the knee which should be prevented by avoiding prolonged or excessive traction through the knee or placement of the pin or wire too near the suprapatellar pouch. This stiffness may be minimized by maintenance of activity of all muscles of the limb during therapy. Intramedullary nail fixation is the method which best preserves muscular power and knee motion.

When seen as a late complication, a trial of quadriceps drill and active movements of the knee is recommended before manipulation under anesthesia or quadriceps lengthening is considered.

THE KNEE

The knee joint marks the articulation of the two longest and strongest bones in the human body; namely, the femur and the tibia. A third bone, the patella, which is the largest sesamoid, forms the third osseous component of this joint. Even though the fibula is frequently involved in injuries to the knee, it is not part of the joint.

The femoral condyles articulate in the shallow fossae on the superior surface of the tibia. These bony fossae are deepened by the superimposed medial and lateral semilunar cartilages.

The strength and stability of this joint do not depend on its bony contours but rather on the strong ligaments that bind the bones together and the powerful muscles that control its movement in different positions of flexion and extension.

Because of the tremendous leverage exerted on this joint by forced movements, injuries to the ligamentous structures and intra-articular menisci are very common. Sports such as football, ice hockey, and skiing, hazardous occupations, and modern rapid transportation all contribute to the increasing number of knee disorders requiring treatment. Injuries of the soft tissues predominate.

Musculature

Attention should be directed first to the quadriceps muscle, so named from its four components: the vastus intermedius, vastus lateralis, vastus medialis, and rectus femoris. This important group of muscles has as its antagonists the hamstring group of muscles, consisting of the biceps femoris, the semimembranosus, and the semitendinosus. These two groups of muscles, the extensors (quadriceps) and the flexors (hamstrings), are reciprocally innervated and act with other muscles, such as the gastrocnemius, popliteus, gracilis, and sartorius, to give the synchronized movements characteristic of normal knee joint function.

Interest is usually centered on the quadriceps. It is therefore necessary to understand evolutionary changes that have taken place in these muscles. In the anthropoid, the knee is somewhat flexed when the animal assumes

Plate 75.—Anatomy of the Knee Joint.

Plate 76.—Anatomy of the Knee Joint.

Courtesy Moseley, H. F. CIBA
CLINICAL SYMPOSIUM 5: 171, 1953

the upright posture. However, man has evolved further and, when erect, the knee is maintained in complete extension. This is possible because of further functional development of the quadriceps. Although not completely true, it is helpful to regard the vastus medialis as the muscle that has developed the function of attaining and maintaining the final 15 degrees of extension. Here is one reason why disorders of the knee cause the joint to assume the position of slight flexion, since a study of evolutionary processes discloses that man loses first those functions last evolved. This also serves to explain the characteristic atrophy of the vastus medialis in chronic disorders of the knee.

Synovial Cavity

The *synovial cavity* of the knee is the most extensive found in any articulation. It consists of two main parts:

1. The inferior cavity arranged in relation to the articular surfaces of the femur, tibia, and patella.

2. The superior cavity, or suprapatellar pouch, forming an upward extension of the joint between the quadriceps tendon and the femur above the articular surface.

The synovial membrane covers the intra-articular fat pads and cruciate ligaments. When distended with effusion, the superior reflection of the suprapatellar pouch will extend about 2-3 inches above the superior pole of the patella. In this area, the membrane, when thickened by chronic disease such as tuberculous synovitis, can be palpated through the atrophied muscles.

Position of Rest

When a tense effusion distends the synovial cavity, the knee is held in a position of 15- to 20-degree flexion. Before chronic stretching of the tissues has occurred, this is the position in which the joint cavity has its maximal capacity to hold fluid. This fact can be confirmed by insertion of a wide-bore needle with manometric connection. When in this position of rest, either extension, flexion, or long-axis traction applied to the joint will increase further the intra-articular tension.

In this posture of 15- to 20-degree flexion, tension in the vastus medialis (which is largely responsible for the last 15 degrees of extension) is reciprocally inhibited, and it rapidly atrophies. *Atrophy of the vastus medialis is therefore a cardinal clinical sign in organic disorders of the knee.*

Ligaments

The important ligaments stabilizing the bones are the medial collateral and cruciate ligaments which require careful description at this point, since they are the ones most frequently deranged by trauma.

Medial Collateral Ligament.—This is the ligament that is most frequently injured. The mechanism is a severe strain caused by forced abduction or external rotation.

This ligament consists of two parts: (1) a short, deep, thick posterior portion and (2) a longer anterior band, approximately 7.5-9 cm in length, extending from the femoral epicondyle and fanning out into a broad expansion on the anteromedial surface of the tibia. This insertion is strengthened by the common tendinous expansion of the sartorius, gracilis, and semitendinosus.

Cruciate Ligaments.—These ligaments are the fibrous bands which stabilize the tibia and femur in their anteroposterior glide upon one another. The *anterior cruciate ligament* is tight on extension and limits excessive anterior mobility of the tibia on the femur. When ruptured, there is increased anterior mobility of the tibia on the femur when tested in flexion.

The *posterior cruciate ligament* limits posterior mobility and is tight on flexion. Rupture of this ligament permits the tibia to assume a position of posterior displacement on the femur when in flexion. When tested clinically by the "drawer sign," there is an increased posterior mobility.

An aid in remembering the anatomy and function of the cruciate ligaments is the mnemonic—ATE A PIE.

Anterior cruciate is
Tight on
Extension and runs from the
Anterior surface of the tibia to the
Posterior part of
Internal surface of the
External condyle of the femur

The posterior cruciate is tight on flexion and runs in the opposite direction

Semilunar Cartilages

These intra-articular menisci develop as a condensation of the mesoderm, dividing the joint into superior and inferior cavities. In time a central division occurs from the development of the ligamentum mucosum, giving rise to a lateral and medial meniscus of solid discoid form. These develop into the semilunar-shaped structures with which we are all acquainted.

The evolution of the medial cartilage tends to be more uniform than that of the lateral cartilage. In the latter, arrests in development account for the various forms of congenital discoid cartilages, which are found almost exclusively on the lateral side.

The menisci differ somewhat in shape. The lateral cartilage constitutes a greater portion of a circle of smaller radius than is the case for the medial meniscus. This corresponds to the differences in the shapes of the femoral condyles, which will be discussed later in relation to the motions of the joint.

The medial meniscus is firmly attached in its posterior portion to the deep surface of the medial collateral ligament, whereas the lateral meniscus is not so closely adherent to the lateral collateral ligament and is therefore more mobile than its counterpart. The tendon of the popliteus muscle bears a close relation to the lateral meniscus. Both cartilages are peripherally attached by the coronary ligaments to the adjacent areas of the upper aspect of the tibia.

Movements of the Knee Joint

This articulation is classed as a hinge joint. However, its movements are more complicated than the flexion and extension of a simple hinge. To help in understanding the movements of the knee, compare them with those of the elbow.

Motion at the elbow consists of two main mechanisms; namely, the *hinge mechanism* between the lower end of the humerus and the greater sigmoid notch of the ulna and

radial head and the *pivot mechanism* between the radial head and the capitellar surface of the humerus and lesser sigmoid notch of the ulna.

These two mechanisms exist in a variant way in the knee joint (Plate 78). Flexion from the position of complete extension occurs as a hinge movement between the femoral condyles and the upper surfaces of the menisci and tibial articular cartilage. At the same time that this hinge movement is occurring, the tibia glides backward, this latter motion taking place between the inferior surface of the menisci and the articular surface of the tibia. Therefore, flexion of the knee is a movement that occurs on a transverse axis of changing position, and at any particular point only a small area of femoral articular cartilage is in contact with a small area of the articular surfaces inferiorly.

At the same time, as flexion occurs, there is also an internal rotation of the tibia through a vertical axis situated in the outer part of the lateral femoral condyle and tibial tuberosity. This internal rotatory movement is reversed in extension. Maximal stability is obtained by this external rotation, which locks the joint on complete extension.

Association of ideas assists in memory. Therefore, one might remember that just as complete elevation of the arm above the head is possible only with external rotation of the humerus, so complete extension of the knee is possible only with external rotation of the tibia on the femur.

The above exposition will explain the reasons for the differences in size and shape of the lateral and medial femoral condyles and menisci. Since the axis of the rotating movement of the tibia on flexion and extension is vertically placed through the outer part of the joint, the medial condyle and menisci must move farther and therefore possess the larger radius of movement.

Besides this movement of rotation, the student should recognize that in the flexed position, a certain amount of rotational and side-to-side motion is possible on clinical examination. This varies in extent when comparing the close knit with the lax-knit type of joint.

Examination of the Knee

This articulation, unlike the hip and shoulder, is superficially placed, and a great deal can be learned on clinical examination by inspection and palpation, as shown in Plates 79 and 80.

Inspection.—The patient may walk with an obvious limp, carrying a cane or crutches. When assisted by a friend on either side, the method of hopping on the sound leg should be noted. Complete absence of weight-bearing and partial flexion of the knee will indicate the acute injury so often seen in the young athlete.

With the patient supine on the examining table and the affected limb next to the examiner, the region of the knee is inspected for obvious deformity. Gross changes due to severe injury will be apparent. The most frequent finding is that the knee is held in the flexed position previously mentioned. Also, the joint is swollen from synovial effusion, the normal hollows superior to and on each side of the patella being lost due to distention.

In injuries by direct violence, contusion of the skin over the patella or in the region of the tibia will be seen. When the injury has occurred several days previously, ecchymoses of varying hues will be present. In chronic disease, as well as in acute derangements of 10 or more days' duration, wasting of the vastus medialis will be perceived by the experienced examiner. Note will be given to the prominence of the superior reflection of the synovial membrane. At this point, the patient may be asked whether he can raise the limb from the couch and whether flexion and extension are possible voluntarily.

Palpation.—The student should first handle the limb to determine the range of passive motion. He should ascertain whether complete extension and flexion are possible, or whether they are limited by pain and muscle spasm in the acute cases, or by contracture in chronic disorders.

During the manipulation, the typical elastic block to complete extension in cases of displaced menisci with the locked knee will be discerned. With the palm of one hand compressing the patella to the femoral articular

area, crepitus will be noted on passive flexion and extension when degenerative changes are present. Fixation of the patella can be demonstrated by attempting side-to-side manipulations of the bone in the chronically stiffened joint.

The *abduction test* is valuable in differentiating lesions of the internal collateral ligament from those of the meniscus. With the knee in complete extension and with the examiner's knee as a fulcrum, a valgus strain is applied to the joint. This will greatly augment pain in the ligamentous injuries, and digital palpation will localize the point of maximal tenderness as being near the femoral epicondyle rather than on the joint line over the medial meniscus. This can be confirmed by forcible external rotation in flexion, when ligamentous injury will present digital tenderness over the femoral origin of the ligament, while joint line tenderness will be maximum with lesions of the meniscus.

McMurray's sign is valuable in posterior tears of the meniscus. With a finger flattened along the joint line, the knee is fully flexed. Rotation of the tibia internally and externally while extending the joint will transmit a clicking sensation to the finger when the torn meniscus moves in and out of place.

The *drawer sign* is diagnostic of associated injuries of the cruciate ligaments. With the knee flexed to a right angle, the tibia is pulled forward and pushed backward. Increased anterior mobility denotes rupture of the anterior cruciate ligament. Increased posterior mobility indicates rupture of the posterior cruciate ligament, while increased anterior and posterior mobility is present when both cruciates have been avulsed. This increased anteroposterior glide present in cruciate ligament avulsions constitutes the *drawer sign*.

Examination for Effusion.—This determination is based on the law of the equal transmission of pressure in all directions when applied to fluid within an enclosed space. Plate 80 shows how one hand compresses the fluid in the suprapatellar pouch, while alternating pressure on the patella causes that bone to tap against the femur. The second method, useful when only a moderate effusion is present, is to apply a finger on each side of

the patella and perceive the transmission of pressure from one side to the other

When a tense effusion is present, examination of the knee may be impossible until the joint has been aspirated. Aspiration is done under local anesthesia from the lateral aspect. It should be noted whether the fluid withdrawn is serous, sanguineous, or pure blood. The presence of blood indicates a severe injury involving the cruciate ligaments or an intra-articular fracture. The settling out of a fatty layer on the top of blood is pathognomonic of an intra-articular fracture, usually of the upper end of the tibia. After aspiration, it is possible to make an adequate examination of the joint.

Palpation of the Suprapatellar Pouch.—Careful examination of this area gives valuable information. Palpation may reveal the presence of a joint mouse most frequently lodged in this recess of the synovial cavity.

Thickening of the membrane in chronic synovitis is best ascertained by rolling the supromedial reflection of this pouch under the fingers placed on the atrophic vastus medialis.

Mensuration.—Careful measurements are valuable additions to the patient's record and are especially easy to obtain in injuries of the knee.

The range of motion is accurately indicated by the goniometer, using the position of full extension as 180 degrees.

Measurement of the circumference of the thigh and calf at fixed points from the superior edge of the patella on each limb will give an exact record of the extent of muscle atrophy.

Radiologic Examination.—X-rays taken in the standard anteroposterior, oblique, and lateral positions are necessary. Tangential views show the opposing articular surfaces of the patella and intercondylar area of the femur. In cases of severe injury with ligamentous avulsion and fracture, examination in the positions of strain after instillation of procaine into the joint will indicate the degree of joint laxity and the extent of displacement before recoil. Arthrography, using contrast media, has proved valuable in cases of doubtful meniscus lesions.

Classification

1. Injuries of the extensor apparatus
 - Hematoma of thigh
 - Rupture of quadriceps expansion
 - Patellar lesions
 - Fractures, stellate or transverse
 - Chondromalacia
 - Dislocations
 - Rupture of patellar ligament
 - Osgood-Schlatter's disease
2. Injuries of other soft tissues
 - Synovitis
 - Hemarthrosis
 - Internal collateral ligament
 - Chronic postural strain and Stieda-Pellegrini's syndrome
 - Cruciate ligaments
 - Semilunar cartilages
 - Bursal lesions
3. Fractures of component bones
 - a. Femur
 - Lower femoral epiphysis
 - Condylar and intercondylar
 - Articular; osteochondritis
 - b. Tibia
 - Bumper fracture
 - Tibial spine
4. Dislocations
 - Knee
 - Patella, see above
5. Arthritides
6. Congenital anomalies

INJURIES OF THE EXTENSOR APPARATUS

Hematoma of the Thigh

Large volumes of extravasated blood may accumulate in the quadriceps mass as a result of a direct blow or kick at football, 500-1,000 ml is not unusual.

Diagnosis.—The history of the injury together with a swollen tender thigh is typical. Fluctuation is present in the early cases.

Treatment.—If seen early, treatment includes applications of a compression bandage, ice bags, and the institution of quadriceps exercises consisting of repeated straight-leg raising, tensing the quadriceps by forcing extension, and contracting and relaxing the muscle groups by alternate gentle flexion and extension. These exercises constitute quadriceps

Plate 79.—Examination of the Knee Joint.

Plate 80.—Examination of the Knee Joint.

drill and should be carried out for 5 minutes on the hour every hour. Early ambulation on crutches is desirable. If seen within 2-3 days aspiration with a wide-bore needle or evacuation through a small incision is indicated. A compression bandage is applied for 12-24 hours followed by quadriceps drill. Bed rest for 2-3 days and then ambulation on crutches and graduation to normal activity is the post-operative routine.

If seen later, the hematoma may be clotted, and it is best to apply hot packs and initiate quadriceps drill. The hematoma begins to liquefy between 10-14 days, and the serum may then be evacuated. If the femoral peri-

osteum has been raised, myositis ossificans sometimes develops. The use of a Thomas caliper to prevent knee movements is then beneficial, and the progress must be followed by x-rays at regular intervals. *Passive movements, which predispose to myositis ossificans, are avoided at all stages.*

Rupture of the Quadriceps Expansion

This corresponds to rupture of the rotator cuff in the shoulder. The tendon ruptures at the critical zone near its insertion on the patella. Degenerative changes constitute the predisposing factor. The central portion, consisting of the tendons of the rectus femoris and vastus intermedius (which corresponds to the supraspinatus tendon) may separate alone, or the expansions of the vasti on the medial and lateral aspects of the patella may separate as well. This major injury corresponds to massive avulsion of the rotator cuff. The cause of such tendon ruptures is a sudden strain in a middle-aged, often overweight patient while endeavoring to prevent a fall. The condition may be bilateral.

Diagnosis.—The diagnosis is often overlooked but can be made readily, if suspected, from the history of a sudden onset due to strain and the inability of the patient to raise the extended leg from the table. The absence of active extension while power of flexion is preserved in a patient with a hemarthrosis and a deep visible and palpable sulcus above the patella is pathognomonic. If seen later, extensive ecchymosis, indicating a severe injury, will be present.

Although radiologic examination may reveal no abnormality, sometimes the lateral view will show an abnormal tilt of the superior pole of the patella away from the intercondylar articular surface. Soft tissue films may disclose the tendinous defect with a distended joint. Late cases present considerable ossification extending from the patella into the area of tendon rupture.

Treatment.—The major avulsions are best treated at the earliest moment by open operation. The hemarthrosis is evacuated and the tendon reattached, sutures passing through drill holes in the patella. When massive ruptures have been neglected, late repair with

Fig 667—Myositis ossificans following hematoma of thigh.

fascia may be indicated if a period of active quadriceps training has failed to restore adequate power to the extensor mechanism.

Patellar Lesions

The patella is the largest sesamoid bone in the body and constitutes a fulcrum over which the quadriceps expansion passes to the patellar ligament and tibial tubercle. It presents a bony barrier to injuries directed from the anterior aspect and determines the normal cosmetic appearance of this region.

The patella is an integral part of the extensor mechanism. It can be removed and the extensor apparatus reconstituted. However, accurate evaluation of knee joint function after its ablation, taking into consideration power, range, speed, and coordination of motion, will disclose that the articulation has lost an important though not essential part of its mechanism.

Fractures

Mechanism.—Fractures of this bone may result from a direct blow or fall whereupon it is crushed against the intercondylar area of the femur. Such forces result in a stellate fracture but it must be stressed that damage to the articular cartilage of the patella and intercondylar surface of the femur may be the most important component of the injury.

Sudden contraction of the quadriceps with a flexed knee may break the patella transversely with minimal or maximal separation of the fragments. The extent of bony separation indicates the degree of rupture of the lateral expansions of the quadriceps. The shape of the patella appears to predispose to knee injury, and some patients are subject to bilateral and even recurrent fractures.

Clinical Picture.—The region of the knee is grossly swollen, and evidence of bruising may be present. The injury may be associated with a wound compounding the fracture or communicating with the prepatellar bursa. Hemarthrosis is usually present. In transverse fractures with separation a groove is palpable between the fragments which increases when the patient flexes the knee or attempts quadriceps contraction.

The patient usually is unable to lift the extended limb.

Diagnosis.—The diagnosis is readily made on the clinical picture. X-ray examination in different planes affords conclusive proof and indicates the degree of comminution and separation.

Treatment.—The perfect result to be obtained from the treatment of patellar fractures is determined by three factors:

1. Restoration of the continuity of the extensor apparatus
2. Preservation of the fulcrum of the patella which gives the power in the final 5 to 10 degrees of extension
3. Re-formation of a smooth gliding articular surface between patella and femur

In stellate or transverse fractures without displacement, this result may be obtained by the use of hot packs, compression bandages, and bed rest for 2-3 days, followed by quadriceps drill and early ambulation in a tubular cast with the knee in a position of complete extension. The cast should be maintained for 4-6 weeks, and this is followed by re-education of knee movements.

Transverse fractures with separation are best treated by open operation. The hemarthrosis is evacuated and the patella and lateral expansions meticulously sutured. The patella must be so approximated as to give a perfect articular surface. Sometimes a small fragment at the upper or lower pole is best excised.

When the patella is comminuted or when a smooth articular surface cannot be obtained, excision of the patella is indicated. The extensor tendons must be plicated and the continuity with the patellar tendon securely restored.

Postoperative therapy consists of a plaster cast with the knee completely extended for 4-6 weeks with quadriceps drill enforced. After splintage is discarded, re-education of knee movements is initiated.

Chondromalacia of the Patella

Chondromalacia of the patella is a clinical entity receiving more and more attention as a cause of internal derangement of the knee. As a result of bruising of its articular surface by a fall or blow on the kneecap, the cartilage

CLINICAL SYMPOSIA 5 171, 1953.

degenerates and sequesters, giving rise to loose body formation. With separation of cartilaginous fragments, recurrent effusions develop and traumatic arthritis ensues.

Clinical Picture.—The patient may be an active youth with symptoms and signs of internal derangement. There may be complaint of pain centrally located in the knee deep to the patella. This is accentuated by movements of the knee with the patella compressed against the femur. Crepitus may be elicited in this maneuver.

An older patient may present with localized patellofemoral arthritis.

part bone to give a smooth surface. In some cases, however, the damage is so severe that excision of the patella must be carried out.

In all cases, a careful search for loose fragments of cartilage is made and their removal from the joint must be complete.

Dislocations

Dislocation of the patella is usually to the lateral side and is predisposed to occur in patients with valgus deformity or when the patella is small, highly placed, and the lateral femoral condylar buttress poorly developed.

Fig 668—Mechanism of recurrent dislocation of patella

Diagnosis.—The study of x-ray films carefully taken to show the articular surface in various planes may disclose irregularities which, with the clinical picture, concludes the diagnosis. The presence of loose bodies in the joint is suggestive.

Treatment.—Exploration of the knee joint is indicated, and all components of the joint must be carefully studied through a medial parapatellar incision.

If the articular surface is not grossly diseased, the cartilage is shaved off down to com-

plete bone to give a smooth surface. In some cases, however, the damage is so severe that excision of the patella must be carried out.

Mechanism.—In most cases the resultant force of the quadriceps contraction tends to displace the patella to the lateral side. In the complete displacement the patella rotates 90 degrees or more around the lateral condyle.

Diagnosis.—When the patella is dislocated, the knee is held locked in a slightly flexed

position. The abnormal position of the patella is seen. Any genu valgum deformity is noted, and x-rays are taken to show the characteristics of the patella and femoral condyle.

Treatment.—Acute dislocation is readily reduced by direct pressure in a medial direction. The patient should then be placed on quadriceps drill to develop the musculature. This should also be initiated in recurrent cases and a firm bandage applied for a period if the patella is unstable.

Fig. 669—Photograph of Osgood-Schlatter's disease

In most recurrent dislocations operation is eventually required. This consists of transposition of the patellar tendon with its tibial attachment into a slot cut more medially on the tibia. The capsule at the same time is plicated on the medial side. This places the line of quadriceps pull more directly in line with its tibial insertion.

Rupture of the Patellar Ligament

This can occur at the patellar or tibial attachment with or without a fragment of bone. The diagnosis is usually obvious. Treatment consists of careful suture, followed by splinting of the knee in extension until firm union has occurred (6-8 weeks).

Osgood-Schlatter's Disease

This is sprain of the patellar tendon attachment to the tibial tubercle. The tubercle develops its ossification as a separate center or as a tongue-shaped extension of the upper tibial epiphysis. This epiphysis fuses at 17-18 years. Before this period and especially from 12-15 years of age, athletic youths may develop pain and swelling of this area associated with limitation of knee movements and consequent limp.

Clinical examination shows a prominence of the tibial tubercle more marked than on

Fig. 670—X ray showing fragmented appearance of tibial tubercle during the period of creeping substitution. The unaffected side is shown for comparison.

the opposite side. The swelling may be red-
dened and tender. All grades of severity are
seen.

X-ray examination may be negative or show
a fragmentation of the tibial tubercle which
with time undergoes the creeping substitution
seen in the osteochondritic process.

Treatment.—This consists of rest to the
part. In mild cases strapping suffices. In severe
cases with separation of the epiphysis, reddening,
and swelling, a tubular cast with the knee
in extension is applied for 6-8 weeks.

If the severe cases are not so treated,
a permanent failure of fusion of the bony
tubercle may result. This is marked in later
years by recurrent pain on excessive use and
limitation of functional capacity. This results
from the sprain of the central attachment of
the quadriceps tendon, the lateral expansion
attachments to the tibia being undisturbed.

X-ray reveals the separated tubercle, and
treatment consists of roughening its deep aspect
and fusing this to the tibia. Excision of the
fragment with suture of the central tendon
to a raw bed on the tibia is an alternative
procedure.

INJURIES OF OTHER SOFT TISSUES

Synovitis

A serous effusion may occur in the knee
as an acute or recurrent condition. The acute
process may result from any irritation to the
synovial membrane resulting from a sprain
or from the presence of some mechanical
derangement in the joint. Loose bodies or
torn semilunar cartilages may be the irritant
factors, and an intra-articular lesion should
always be suspected in the recurrent cases.

Treatment.—Aspiration of the fluid, fol-
lowed by the application of a firm elastic
support and quadriceps drill, is the treatment
of choice. Recurrent effusions may require
exploration of the joint to ascertain the cause.

Hemarthrosis

The knee may fill with blood as a result
of a severe sprain, rupture of cruciate ligaments,
or fracture communicating with the joint. A
tense joint may develop rapidly within one
hour, whereas serous effusions take the greater
part of a day.

Clinically, the joint is held in the position
of maximum joint capacity, i.e., 160 degrees.
There are diffuse tenderness and considerable
pain on attempted movement. X-ray should be
taken to exclude bony injury.

Treatment.—Aspiration should be per-
formed. When the joint is lax, further ex-
amination may be carried out to ascertain
the extent of injury. A firm bandage and
quadriceps drill is the routine postoperative
therapy. Exploration may be advisable.

Internal Collateral Ligament

This ligament is subject to acute partial
and complete tears. Many cases of prolonged
disability of the knee are due to chronic pos-
tural strain of its femoral attachment. Calcified
deposits may occur at this point and give
rise to a syndrome named after Stieda and
Pellegrini.

Mechanism of Rupture.—The femoral is
much weaker than the broad tibial attachment
of this ligament and separates partially or
completely in varying degrees of valgus strain
of the joint. This constitutes the first stage,
which passes on to external condylar or tibial
fractures or lateral dislocations of the knee.

The causative force may be a tackle at foot-
ball from the side or a bumper injury from
a car.

Diagnosis.—This is made on the type of
injury and the location of the tender point
on the femoral condyle. In mild cases this may
constitute the clinical picture. In severe cases
the ligament is completely separated. Lateral
instability is present. A serous effusion or
hemarthrosis indicates the serious nature of
the injury. The knee is held flexed and the
patient bears weight with pain and a limp.

Treatment.—Mild cases require little more
than a firm support. Complete ruptures with
separation are best sutured by open operation
followed by plaster immobilization for 4-6
weeks and concomitant quadriceps drill.

The majority of cases present an inter-
mediate group. No instability is present, but
the final 20 degrees of extension and complete
flexion are painful. Treatment consists of
heat to the affected area, quadriceps drill, and
firm bandaging. Infiltration with 1% procaine
assists both the diagnosis and treatment.

Ambulation on crutches may be helpful for a week or more. Elevation of the inner side of the heel $\frac{3}{16}$ " and in-toeing will relieve the strain when weight-bearing begins.

Chronic Postural Strain and Stieda-Pellegrini's Syndrome

Both these clinical entities present the same clinical picture. They both occur in valgus strain of the knee of chronic type, whether in women of the sthenic type from the relative genu valgum or from the transmitted strain of pes valgus.

The patient complains of pain in the knee with inability to flex or extend the joint completely. There is the consequent limp, increasing with overuse. Tenderness is present over the femoral attachment and along the ligament.

X-rays may show degenerative arthritic changes. In the latter syndrome, an area of calcification will be seen at the femoral attachment.

Treatment.—This consists of diminishing the valgus strain, which may be accomplished by general measures such as the reduction of excessive weight. Raising the inner side of the heel and sole of shoes $\frac{3}{16}$ " and teaching the patient to in-toe will diminish the aggravation. With this is associated re-education of the muscular balance to both lower limbs working from the foot musculature upward. Local heat is an adjuvant, as are active movements of the knee on bicycle or sliding seat.

Cruciate Ligaments

The cruciate ligaments are ruptured in marked displacements of the tibia on the femur. They are therefore associated lesions in the various dislocations.

The *anterior cruciate* is tight in extension and limits hyperextension. It is injured in forcible hyperextension of the joint.

The *posterior cruciate* is tight in flexion and is injured in the dashboard type of injury when the flexed tibia is driven backward on the femur.

Clinical Picture.—The injury is usually a severe one with hemarthrosis present. Rupture of the cruciates results in an increased

anteroposterior glide of the tibia on the femur in the flexed position.

Rupture of the anterior alone permits increased forward movement; rupture of the posterior alone increases posterior movement.

Treatment.—This is determined by the concomitant injuries. Immobilization of the joint in a tubular plaster for 3 months associated with routine quadriceps drill is the most effective initial treatment. If associated with a dislocation of the knee, open operative suture of the ruptured soft tissue structures is indicated.

Late cases must be evaluated carefully and a thorough trial made of the stabilizing influence of quadriceps re-education before operative reconstruction is considered.

Semilunar Cartilages

Injuries of the menisci constitute one of the most frequent and interesting groups of internal derangements.

Development.—The semilunar cartilages originate as a plate of mesoderm, which divides the joint into superior and inferior compartments. Later this plate is divided centrally by the ligamentum mucosum into a lateral and medial disc. The medial disc differentiates more rapidly and completely than the lateral disc into the semilunar shaped structures, which serve to deepen the sockets for the femoral condyles. Arrest in differentiation is more common in the lateral meniscus, which may present various forms to give the congenital discoid cartilage.

Mechanism of Injury.—The internal cartilage is injured 7-8 times more frequently than the lateral cartilage. This is because there is more tendency to an external rotation strain of the tibia on the femur in the flexed position of the knee. During this movement the internal cartilage is drawn between the articulating surfaces and, if ground between these surfaces with a shearing force, is fractured. Various types of meniscus injuries are produced as illustrated (see Plate 82).

The external cartilage is injured by an internal rotation strain with adduction of the tibia on the femur.

Clinical Picture.—The patient is typically a young athlete who suffered a severe rota-

tion strain of the knee during a football game. He felt a sickening pain at the time and possibly heard or felt a click in his knee. The knee locked in a position of flexion and he was unable to carry on. When seen shortly afterward the patient is in pain. The knee is held by muscle spasm at 140-150 degrees, and attempts to walk on it or straighten it cause severe pain. Palpation over the inner joint line discloses a point of maximum tenderness.

Diagnosis.—This is made on the typical clinical picture with the locked knee and tenderness localized to the joint line.

Manipulation of the knee through a full range of movement under anesthesia unlocks the joint and adds confirmation to the diagnosis. X-rays in these cases disclose no bone injury but are taken routinely to exclude articular fractures or loose bodies in the joint.

The case may be seen later, when the displaced cartilage has been reduced. Here the diagnosis may be more difficult. Characteristic findings are atrophy of the vastus internus associated with effusions in the joint and joint line tenderness.

Manipulation of the knee in flexion and extension with varying degrees of rotation may elicit a click to the fingers placed along the joint line on the affected side. This test described by McMurray is of great diagnostic significance in doubtful cases. There may be a history of recurrent locking, recurrent effusion, or repeated giving way of the joint. In tears of the lateral meniscus, a sudden click in the final degrees of voluntary extension is most significant.

Arthrograms with contrast media (8-10 ml 35% Diodrast) may be helpful in cases of doubt.

Differential Diagnosis.—

1. *Quadriceps insufficiency* After all injuries of the knee, there is rapid atrophy of the quadriceps unless this is prevented by muscular drill. Insufficiency of the extensor mechanism can result in recurrent effusion, giving way of the knee, and all the points in the clinical picture of internal derangement. When suspected as the cause, the therapeutic trial of quadriceps drill is prescribed as a diagnostic and curative measure.

2. *Sprain of the internal collateral ligament* is the most important injury to differentiate in acute cases from injuries to the internal meniscus. The mechanism of injury here is a direct abduction or valgus strain, whereas the injury of the cartilage is caused by a rotation strain. Confusion arises where the two are associated.

A.

B.

Fig 671—Cyst of external cartilage. A, Clinical photograph B, Specimen

The point of maximum tenderness is over the femoral attachment in the ligamentous injuries, and procaine infiltration may be used to abolish the local pain and demonstrate the absence of mechanical block to knee movements. In cartilage injuries the tenderness is directly over the joint line and the McMurray test will be helpful in differentiation.

3 *Osteochondritis of the femoral condyle and chondromalacia of the patella* must be considered. X-ray examination disclosing the defect of articular cartilage and the presence of loose bodies in the joint demonstrate the chief differentiating points.

4 *Hypertrophy of the infrapatellar pad of fat* may cause the symptoms of internal derangement when villous processes are nipped in the joint. Arthrotomy often is required to establish the diagnosis.

5 *Loose bodies*. Fibrous, cartilaginous and osseous loose bodies can give all the signs of internal derangement.

6 *Cysts of the semilunar cartilages*. Ganglionic degeneration which chiefly occurs in the lateral meniscus will be indicated by the tense local swelling on the joint line.

Treatment.—The locked knee caused by the displaced cartilage should be manipulated under anesthesia and the cartilage replaced. The joint is put through its full range of flexion and extension in varying degrees of rotation. This usually results in replacement of the displaced fragment.

Following manipulation a firm bandage is applied and quadriceps drill is initiated.

In recurrent cases and in cases of initial injury where the diagnosis is certain, arthrotomy with complete removal of the cartilage is the ideal therapy. Postoperative treatment consists of immediate quadriceps drill. Ambulation on crutches may begin as soon as the patient feels able. Stitches are removed on the 7th-8th day and flexion exercises begin between the 8th and 10th days. Good function is present after 3-6 weeks.

Bursal Lesions

Numerous bursae exist around the knee, and each one can be the site of an inflammatory process. The prepatellar and semimembranosus bursae are of most interest.

Prepatellar Bursitis.—This bursa is based on the patellar ligament and lower half of the patella and enables the skin and subcutaneous tissue of the kneeling surface to slide over the underlying hard tissues.

In the days before household appliances removed the hard work from domestic cleaning, the amateur housemaid who attempted the wide-swath technique of scrubbing would suffer a traumatic bursitis in this "buffer" between patella and floor. Thus, "housemaid's knee" received its designation. It consisted of a painful swelling of the prepatellar bursa due to repeated trauma. Today it is occasionally seen in those forced to kneel or it can follow a direct blow or a fall, or it may be associated with stellate fracture of the patella.

Gout may produce a bursitis at this site, and bilateral chronically thickened bursae may be due to gummatus infiltration. Syphilitic bursitis is much less common because of the present efficient primary treatment of this disease.

Treatment of traumatic bursitis consists of removing the cause. If the bursa is distended, the sanguineous fluid should be aspirated and a pressure bandage applied. When the disorder is recurrent or chronic, excision of the entire bursa is the treatment of choice.

Semimembranosus Bursitis.—This bursa is situated in relation to the semimembranosus tendon, the adjacent posteromedial capsule of the joint, and the medial head of gastrocnemius. In some cases the bursa communicates with the knee joint. Indeed, Wilson has referred to it as a "posterior herniation" of the joint. Clinically, the student should recognize two groups of patients who seek advice for a painful distention of this sac.

Most commonly the patient is a youth below the age of puberty who presents pain in the popliteal area extending into the upper calf and lower thigh. He complains that his knee feels stiff and that pain and stiffness are more severe after activity. The parent may have also noted a swelling at the back of the knee.

Examination discloses an ovoid, tense swelling somewhat to the medial side of the popliteal space which is prominent when the knee is in full extension. On palpation a tense swelling may be felt. On flexion it seems to dis-

appear. Considering these points, diagnosis is readily made.

The same clinical picture may be found in a patient past middle age who has an effusion into the knee joint associated with degenerative or other forms of arthritis, posterior meniscus tears, or following arthroscopy. Tense swelling in the popliteal space is noted on examination. Here the semimembranosus bursa communicates with the joint and acts as a blow valve for release of intra-articular pressure (Baker cyst).

The treatment in the two cases is different. In the primary bursitis of the youth, excision will produce a cure. In the bursal involvement secondary to articular disease the treatment is that of the primary lesion. Excision of the bursa alone may result in a synovial fistula.

FRACTURES OF COMPONENT BONES

Femur

Lower Femoral Epiphysis

Separation of the lower femoral epiphysis occurs before its fusion (18-20 years). The mechanism of injury is a forcible hyperextension by which the epiphysis displaces forward with the leg, the lower end of the femoral shaft projecting backward into the popliteal space. As in supracondylar fractures, there is a danger of injury to the popliteal vessels and nerves by the prominent shaft fragment. These epiphyseal injuries are uncommon but must be considered serious because of their tendency to interfere with growth and thus shorten or deform the limb.

Reduction.—Manipulation in the flexed position of the knee with traction on the leg and countertraction to the thigh and direct pressure backward on the displaced epiphysis secures an easy replacement.

The limb is splinted in a plaster cast with the knee at a right angle for 4 weeks. The cast is then changed to one with the knee in slight flexion for a further 3-4 weeks. When reduction is unstable, or as an alternative treatment in later adolescence, internal fixation by two wires inserted in cruciate manner may be employed. Avoidance of weight-bearing for 3 months by ambulation on crutches tends to lessen the tendency to premature synostosis.

Condylar and Intercondylar Fractures

These fractures are serious because of their involvement of this weight-bearing joint and the tendency to restriction of knee movements as a complication.

Mechanism.—Falls from a height, a direct blow, or valgus or varus strain gives the various types of fracture. Shearing off of one condyle is most commonly produced by forceful displacement of the leg to the corresponding side associated with a compression force through the knee by the body weight.

Clinical Picture.—The knee presents a grossly swollen appearance with marked hemarthrosis. X-rays disclose the site of fracture and the displacements.

Treatment.—Aspiration of the hemarthrosis is beneficial. Reduction must be anatomic. If this is possible through tibial skeletal traction and external compression, conservative treatment is indicated. In the grossly displaced fractures, open operation with evacuation of extravasated blood and internal fixation by screw or bolt, securing meticulous alignment of joint surfaces, is the ideal treatment.

Articular Fractures (Osteochondritis Dissecans, Paget's Quiet Necrosis)

This is a specific entity causing internal derangement of the knee. It is one of the group designated *osteochondritis* and in the knee most commonly occurs on the anterolateral aspect of the medial femoral condyle. Most authorities regard the etiology as traumatic. An acute articular fracture may be produced possibly by pressure of the cruciate ligament in a severe rotatory strain. Possibly a contusion through the patella may be the mechanism. Following such an injury an area of cartilage and underlying bone begins to sequester, and the patient may be seen either before or after the separation of the fragment. When first separated, there is cartilage on the one side and bone on the other. As time passes, fibrocartilage forms over the whole surface, giving a uniform appearance to the loose body when seen at operation.

Clinical Picture.—The patient is a young male of athletic habits, who gives a history

of injury to his knee some months previously. He now complains of the typical signs of internal derangement, i.e., recurrent effusion, weakness, locking, or giving way.

X-ray examination is conclusive. A loose body is seen when separation is complete. In earlier cases the lateral view shows the sequestering fragment on the medial condyle.

Treatment.—Exploration is indicated. If the fragment is loose, it is removed and the joint thoroughly searched for other loose bodies. The condylar area is examined. Usually no surgical treatment is required to the healing area. If the fragment is in the process of separating, it should be removed and the area smoothed with gouge and chisel.

often a longitudinal fracture makes communication with the joint.

When the bumper strikes from the lateral or anterolateral aspect, a valgus strain of the knee develops, and the tibial tuberosity on the outer side is depressed and sheared off. The varying stages of injury are shown in Plate 84.

Clinical Picture.—This is similar to that presented by femoral condylar fractures. A hemarthrosis is usually present.

Treatment.—In cases without displacement of the tibial articular surface, aspiration of the hemarthrosis, manipulative reduction by traction in varus position, and compression of the tuberosities when spread, followed by plaster immobilization in this position, are used. Three

Fig. 672.—Osteochondritis dissecans

Tibia

Bumper Fracture

Bumper fracture is so named because of the frequency with which it is caused by the car bumper in street accidents. When the leg is struck from the anterior aspect, the tibia is fractured just below the articular margin, and

to 4 weeks' immobilization is an average time, and this is followed by re education of knee function.

Where the lateral tuberosity is markedly displaced, open operation by a lateral parapatellar incision is performed. The displaced lateral meniscus is removed and the articular surface realigned. The limb is immobilized in varus

position in full extension for six weeks. Re-education of knee movements follows. Weight-bearing in the displaced articular fractures is best avoided for 3-4 months to minimize the traumatic arthritis.

Tibial Spine

Avulsion of the tibial spine occurs with anterior cruciate injuries. The fragment is displaced laterally and wedges between the lateral condyle and tibia, preventing complete extension.

The diagnosis is made by x-ray examination which demonstrates the displaced fragment.

Treatment.—Manipulation of the knee into complete extension and immobilization in a plaster cast for 6-8 weeks in this position may suffice. Open operation with replacement of the fragment and suture may be preferred. The bony fragment may be excised.

DISLOCATIONS OF THE KNEE

The knee is not frequently dislocated. The causative force may be direct to the upper end of the tibia or indirect through the leg. Lateral dislocation is the most common, although anterior and posterior displacements of the tibia on femur occur.

Severe capsular and ligamentous damage results. The cruciates are disrupted.

The serious nature is due to frequent pressure on the popliteal vessels, leading to gangrene. This occurs from the damage of the initial injury and sometimes is due to delayed reduction.

Clinical Picture.—The severe deformity is easily recognized. Careful examination to ascertain vascular and nervous injury is essential. X-rays are important.

Treatment.—The earliest possible reduction is imperative, and this is readily obtained under general or spinal anesthesia. If an anesthetic is not available, reduction should be attempted as a first-aid measure, using gentle continuous traction with the knee at 90 degrees, associated with pressure on the displaced tibia. Open operative suture of the torn capsule and ligaments is being used more frequently on these cases.

Postoperative therapy consists of protection of the capsular tissues from strain until well healed (3 months), associated with quadriceps drill.

ARTHRITIDES

The knee joint is frequently involved in the various forms of arthritis found in other joints. A simple classification is as follows:

1. Traumatic arthritis, including the stiff knee from quadriceps fixation
2. Degenerative or osteoarthritis
3. Infective arthritis, including pyogenic and specific types
4. Rheumatic and rheumatoid
5. Various other types, including gouty arthritis

throughout the period of immobilization, by keeping the patella mobile, and by the avoidance of excessive traction through the joint and of prolonged fixation in splints.

The improvement obtainable in cases of *degenerative arthritis* and *osteoarthritis* has been most interesting. The x-rays here give the diagnosis when characteristic osteophytic formations are found. Weight reduction, physiotherapy, and intra-articular hydrocortisone give marked symptomatic relief in a large proportion of cases.

CONGENITAL ANOMALIES

To complete the picture, the three common anomalies should be mentioned, i.e., *genu valgum* (knock-knee), *genu varum* (bowlegs), and *genu recurvatum* (hyperextension, bandy legs), which can be greatly helped by orthopedic procedures applied in the early stages of the deformities.

SUMMARY

Disorders of the knee have been considered largely from the point of view of the derange-

ments characteristic of this articulation. The student should again be reminded of the importance of the extensor musculature in maintaining the stability and movements of the knee joint, and he will greatly improve the results in these disorders by enforcing quadriceps exercises in all cases of traumatic disorders. Resistance exercises will also assist the final rehabilitation of these common clinical problems.

TIBIA AND FIBULA

Fractures of the tibia and fibula are of frequent occurrence. The subcutaneous position of the tibia accounts for the fact that its fractures are more often open or compound in nature than those of any other major bone.

Mechanism.—Fracture of either bone singly is usually the result of direct trauma. Both bones may be broken by direct or indirect violence. Direct violence gives rise to transverse fractures at the same level and such may be directly compounded. Indirect violence accounts for the spiral types at varying levels.

Fig. 673 --X-rays of fracture of tibia and fibula immediately after plating and 11 months later, showing clinical union.

and the compounding occurs when a sharp spicule of bone penetrates the skin from within.

Displacement is frequent and overlap occurs from muscular spasm. The oblique fracture is especially prone to interposition of soft parts and is unstable after manipulative reduction.

Clinical Picture.—The nature of the accident determines the clinical picture. Fracture of a single bone causes little alteration in the normal contour of the leg, but involvement of both bones may be accompanied by considerable deformity.

The presence of a surface wound and the degree of soiling must be carefully noted.

X-rays show the type of fracture and presence of comminution.

Treatment.—Fractures of the tibia and fibula are serious injuries because of the time required to secure union. This time factor in-

creases as the line of fracture is placed lower in the tibia. The upper third consists of cancellous bone and is surrounded on two thirds of its surface with muscles. The blood supply is good to both fragments. The lower third has little muscle in relation to its surface, tendons having arisen to pass into the foot. The bone has a poor blood supply and little cancellous tissue. The middle third is intermediate in this respect. The presence, therefore, of butterfly fragments devoid of circulation in fractures in the lower half indicates a prolonged period before union.

Four methods of treatment are available.

- 1 Manipulation and plaster cast
- 2 Skeletal traction
- 3 Open operation with internal fixation
- 4 External skeletal fixation

Manipulation and Plaster Cast.—Fracture of the fibula alone requires little treatment apart

Fig 674—A and B, Gross open fracture of tibia and fibula treated by debridement, primary suture, and skeletal traction until wounds healed.

C and D, Similar anterior and lateral views 3 months after intramedullary nailing (Lottes' nail) and cancellous bone chips to the area of the freshened bone ends.

from protection. The tibia affords adequate splinting.

Fracture of the tibia alone without displacement is best treated in a mid thigh cast with the knee slightly flexed and foot at a right angle.

Fractures of the tibia and fibula without displacement, or those in the young or adult that are transverse and stable after manipulation, can be treated in a similar way.

Skeletal Traction—Displaced fractures of the tibia and fibula, especially if oblique or comminuted, can be well treated by skeletal traction through the os calcis on a Braun splint. (See general section on Fractures.) Preliminary manipulation under anesthesia is used to obtain alignment.

Weights vary from 6-12 pounds, and the position is followed by x-rays. After 3-4 weeks the limb is placed in a cast from mid thigh to toes, and ambulation on crutches is begun.

Internal Fixation—In cases of fracture of both bones resisting reduction by manipulation or traction, or when compounded or both limbs are fractured, or other injuries justify, open operative correction and fixation by screws, plates, or intramedullary nail is used. Post-operative therapy includes protection by plaster cast and ambulation on crutches.

External Skeletal Fixation—This method has been successfully used for displaced fractures of both bones.

Time Factor—In all cases a period of 12-16 weeks is required, depending upon the patient's age and the position of fracture. Fractures in the lower third in the older patient require even longer immobilization.

Complications.—

Delayed Union—Delayed union is difficult of definition but in the case of tibial fractures may be said to be present when movement still persists on changing the cast between 3-4 months. When this is found, it is wise to accelerate healing by the application of an onlay bone graft to the anterolateral surface or by a sliding bone graft on the anteromedial surface.

Nonunion—When clinical examination after 6 months discloses movement at the site of fracture, and x-rays show sclerosis of the bone ends and minimal callus, union should be

assisted by removing the scar tissue and metallic fixation if present. This is followed by application of a sliding or onlay bone graft. Cancellous bone can be placed around the fracture line. Adequate plaster splintage is required postoperatively. *Delayed and nonunion of tibial fractures may be caused by an intact fibula which prevents contact compression of the fracture surfaces. When such a problem exists, an oblique osteotomy of the fibula should be performed.*

In both delayed union and nonunion, general treatment directed to correct dietary or mineral deficiency should be instituted.

Chronic Osteomyelitis—This complication of open fractures involving the tibia, lessened by chemotherapy, is best treated by saucer-

Fig. 675—Fracture through area of saucerization which had been completely healed with split thickness skin graft.

zation of the diseased bone and application of a split-thickness skin graft. Cancellous bone may be used later to fill cavities. Plastic procedures supplement the initial treatment.

ANKLE AND FOOT

TRAUMATIC DISORDERS OF THE ANKLE AND FOOT

Anatomic Considerations

Osseous Components (Plate 86)

The foot is composed of 14 phalangeal, 5 metatarsal, and 7 tarsal bones, articulating through the talus, with the mortise of the ankle joint formed by the lower ends of the tibia and fibula. Accessory bones of minor clinical significance are also present.

The foot has a main longitudinal arch, of which the talus is the keystone. The calcaneus forms the posterior segment. The anterior segment is best regarded as composed of two functional components, a *medial component* which is mostly concerned with propulsion and a *lateral component* which chiefly serves for balance.

In the erect posture the body weight is transmitted through the ankle joint to the foot. Depending on the stance, the weight is largely borne by the heel and ball of the great toe, with the lateral border of the foot, the lateral metatarsal heads, and the toes acting for balance. In walking, the heel first receives the weight, which is transferred to the ball of the great toe as plantar flexion occurs. As the heel leaves the ground, the whole weight is finally taken on this part of the *forefoot*.

Ligaments (Plate 87)

The ankle and knee are the articulations most prone to ligamentous sprains, and such disorders have the greatest practical significance. For the understanding of sprains, whether or not associated with the fractures or fracture-dislocations, detailed knowledge is necessary of the interosseous relationships and ligamentous attachments.

Most important in this respect are the interosseous ligament and membrane and the anterior and posterior tibiofibular ligaments strengthening the capsule of the inferior tibiofibular articulation. These fibrous bands, together with the external and internal collateral ligaments, maintain the integrity of the ankle mortise.

The Interosseous Ligament and Membrane.—The interosseous ligament binds the lower ends of the tibia and fibula together and, with the anterior and posterior tibiofibular ligaments, stabilizes the inferior tibiofibular syndesmosis. The fibers of the interosseous ligament run from above outward and downward from tibia to fibula, and this ligament is continuous above with the interosseous membrane whose fibers run in the same general direction. The interosseous membrane functions to prevent bending of the fibula when under strain.

The interosseous ligament and membrane are torn in diastasis of the inferior tibiofibular syndesmosis.

Anterior Tibiofibular Ligament.—The fibers of this ligament have a course downward and outward from the tibia to the fibula. It is ruptured in diastasis of the inferior tibiofibular articulation due to abduction force. When the deforming force is carried to the extreme, there is an associated rupture of the interosseous ligament and membrane with fracture of the fibula 3" or more from its tip (*Dupuytren's fracture*).

Posterior Tibiofibular Ligament.—This fibrous band corresponds to its anterior counterpart in direction of fibers. In spiral fractures of the fibula due to an external rotation force, this posterior ligament remains intact, while the anterior is ruptured. In complete diastasis both the anterior and posterior ligaments are torn.

External Collateral Ligament.—This ligament is the one most frequently involved in soft tissue disorders of the ankle. It consists of three distinct bands:

1. The anterior talofibular ligament passing from the tip of the fibula to the base of the neck of the talus on its lateral aspect
2. The calcaneofibular ligament extending downward and slightly posteriorly to the calcaneus

3. The posterior talofibular ligament passing horizontally backward to insert on the tubercle of the talus

The anterior talofibular ligament and the calcaneofibular ligament are the bands avulsed by forced inversion. The rupture is most commonly at the fibular attachment and the tip of the external malleolus may be avulsed at the time of injury. This injury permits subluxation of the ankle and, if neglected, gives rise to recurrent subluxation of the joint.

Internal Collateral or Deltoid Ligament.—The deltoid ligament is really the strong fibers of the medial portion of the articular capsule of the ankle joint. Its fibers course from the internal malleolus to the navicular, sustentaculum tali, and posterior area of the talus. It forms four main bands, i.e., the tibionavicular, the anterior talotibial, the calcaneotibial, and the posterior talotibial ligaments.

This ligament is ruptured by forces of abduction or external rotation, and the tear usually takes place at its tibial attachment. The insertion of the ligament to the tibial malleolus is so strong that avulsion of the internal malleolus is the rule.

Muscles and Their Functions

(Plates 88-90)

A simple basic comprehension of the muscle balance of the foot can be gained by examining some of the important muscles and their functions.

Gastrocnemius and Soleus.—These calf muscles act through the tendo achillis to produce plantar flexion of the foot and of the lateral component of the anterior segment of the longitudinal arch. When contraction of the muscles is carried further, it produces an adduction and inversion of the forefoot.

The proximal attachment of the soleus to the tibia, in contradistinction to the origin of the gastrocnemius on the femoral condyles, enables the above function to be carried out when the knee is in flexion.

Peroneus Longus.—This muscle also functions to secure plantar flexion. It balances the tendency to inversion of the lateral component of the forefoot, just described, by a force of eversion applied to the medial component of the forefoot exerted through the head of the

first metatarsal. The ball of the great toe joint is therefore held firmly to the ground, affording the fulcrum necessary for propulsion.

Tibialis Anterior.—This powerful muscle produces dorsiflexion and inversion of the foot, in which movement it is assisted by the extensor hallucis longus acting chiefly on the proximal phalanx of the great toe.

Extensor Digitorum Longus.—This muscle acts as a balancing force with the tibialis anterior and extensor hallucis longus as a dorsiflexor of the foot. By its power of eversion of the forefoot, it counterbalances their action of inversion, thus assisting the movement of dorsiflexion.

Tibialis Posterior and Peroneus Brevis.—The first of these two muscles produces adduction and the second produces abduction of the forefoot. Both assist in plantar flexion.

Abductor Hallucis, Flexor Hallucis Brevis, and Adductor Hallucis.—These all act in forcible plantar flexion of the proximal phalanx of the great toe, leaving the distal phalanx lax and thus facilitating propulsion. The muscles moving the toes correspond to those for the fingers. It should be reiterated that the toes, apart from the hallux, are chiefly concerned with balance.

Muscles Acting in Walking.—As the heel strikes the ground, tension in the dorsiflexors (tibialis anterior, extensor digitorum communis, and extensor hallucis longus) holds the foot approximately at right angles to the leg until the weight is transferred to the ball of the foot. Then the gastrocnemius and soleus lift the heel. Assisting in this are the peroneus longus which depresses the medial component of the foot and the adductor, the abductor, and the flexor hallucis brevis which flex the great toe to give the final "push off."

General Examination of the Ankle and Foot

This region should receive careful inspection with the patient standing, walking, and sitting. Any deformity or abnormality should be noted. The skin and underlying soft tissues of the lower extremities afford a good indication of the circulatory status, impairment being revealed by dependent edema or discoloration. The dorsalis pedis and posterior tibial arteries

must always be palpated to determine relative patency.

The movements of the ankle should be recorded, remembering the variability between the hypermobile and stable types. Dorsiflexion of 10-20 degrees and plantar flexion of 25-35 degrees constitute an average range. Dorsiflexion will be limited in the female patient accustomed to high heels, in whom a contracture of the calf muscles is present.

The subtalar joint between the talus and the calcaneus is tested by a side-to-side rocking movement to elicit pain or demonstrate stiffness. This articulation is the shock absorber of the foot, enabling adjustment when traversing irregular ground. The midtarsal joints should be moved to note their range in adduction and abduction.

Sprains (Plate 91)

A *sprain* may be defined as the rupture of some or all of the fibers of a ligament. If the injury does not result in instability of the joint, the sprain may be termed *minor*, but if instability results, the designation *major* is given. When the ligament itself does not rupture but avulses the fragment of bone to which it is attached, a *sprain fracture* has occurred.

Inspection.—The ankle region is observed to note the presence of general or localized swelling, discoloration, or blister formation.

Palpation.—The areas of the malleoli and tarsal bones are palpated to localize the points of maximum tenderness, indicating the points of ligamentous rupture.

Manipulation.—The foot is moved on the ankle into external rotation, internal rotation, abduction, adduction, plantar flexion, and dorsiflexion to bring out the movements that cause pain. This information is correlated with the findings on palpation. It may be necessary to infiltrate the painful torn ligaments with a local anesthetic before manipulation can be properly performed. Excessive mobility will indicate an instability from a major sprain. Separation of a fragment of bone will indicate a sprain fracture. X-rays taken in positions of strain will add confirmatory information.

Treatment of Minor Sprains.—Swelling due to minor sprains may be controlled by the

immediate application of a pressure dressing, a cold pack, and rest from weight-bearing. Strapping is applied in such a manner as to relax the affected ligament. Procaine infiltration will alleviate pain and facilitate ambulation. Infra-red heat, massage, and active exercises will secure a rapid recovery.

Major Sprains

Two important groups of major sprains and sprain fractures of the ankle occur. These are *inversion sprains*, injuring the fibulocalcaneal and anterior fibulotalar components of the external collateral ligament, and *abduction sprains*, involving the superior attachment of the deltoid or internal collateral ligament.

Major Inversion Sprains.—Close-knit and lax types of joints are found in the articulations of the ankle and foot. The *lax joint mechanism* gives rise to the hypermobile ankle and tarsal joints found in slender individuals. Bonnin places the incidence at 4%. Such persons have feet that are hypermobile on inversion, and the foot can be moved into a position so that the sole is inverted at practically a right angle with the ground. Examination of the lateral aspect shows the prominence of the fibular malleolus, the talus, and the cuboid. In the stable foot, this marked inversion is prevented by the fibulocalcaneal ligament which stands out as a firm, palpable band when such a movement is forced.

A major sprain or sprain fracture of this ligament in the stable foot results in the same clinical appearance found normally in the hypermobile foot. The foot can be markedly inverted. In the acute lesion, the diagnosis is made by finding acute tenderness and swelling over the tip of the lateral malleolus. Pain often prevents the foot from being placed in the position of the complete displacement that occurred at the time of the accident. Satisfactory evaluation requires local procaine infiltration of the area, with radiologic examination in the position of strain. Such investigation will disclose subluxation of the talus from the ankle mortise (Fig 676).

Treatment.—Diagnosis of a major sprain of the fibulocalcaneal ligament necessitates plaster immobilization for 8-12 weeks with the ligament in a position of relaxation. Because of

this prolonged period many surgeons consider that primary suture is justified and, with more exact diagnosis in the early stages, this form of initial treatment is more and more frequently performed. Ambulation is permitted in a below-knee walking cast. Following the period of plaster immobilization, an elastic bandage or stocking should be worn and physiotherapy given.

habitus or as a result of previous fibulocalcaneal rupture, there is the clinical syndrome of recurrent weakness, giving way, going over, or further stages of inversion sprain associated with pain and swelling.

In the patients without an initial major sprain, palliative treatment consists of a laced ankle support, care to avoid worn shoe heels, and a raise on the outer side of the heel and

Fig. 676—Subluxation of left ankle with avulsion of the anterior fibulotalar and fibulocalcaneal ligaments. Both the left and right ankles are in forced inversion, demonstrating the subluxation on the left side when compared to the normal right ankle.

Recurrent Subluxation of the Ankle—The stable ankle has the taut fibulocalcaneal ligament and adequate muscle balance to maintain this state. The hypermobile or lax joint has a relaxed fibulocalcaneal ligament due to inherent laxity in the asthenic individual or to previous rupture with inadequate treatment in cases resulting from trauma. In the slender type with powerful muscle balance, as found in ballet and acrobatic dancers, prevention of sprains is due to muscular control. In those individuals with poorly developed musculature who have hypermobile ankles as part of their

sole, associated with active exercises directed especially to develop the muscles, such as the peroneus longus and brevis, which oppose the inversion of the foot produced by the tibialis anterior and posterior and triceps surae.

In cases resulting from a major sprain of the fibulocalcaneal ligament, primary treatment by adequate plaster immobilization, with or without operative suture, will prevent its development. In neglected cases, reconstruction of the ligament by tenodesis, using part of the peroneus brevis tendon (Watson-Jones) or with fascia lata, has given satisfactory results.

Major Abduction Sprains.—Major sprains of the abduction types are second in frequency of the neglected traumatic disorders of the ankle, and they often lead to disabling sequelae.

When the foot is forcibly abducted, tension develops in the internal collateral or deltoid ligament. A minor sprain may result, which is readily relieved by bandaging the part with the foot adducted, thus relaxing the injured ligamentous fibers.

Should the deforming force continue beyond this point, the ligament may rupture near its periosteal attachment or, more commonly, may avulse a varying portion of the internal malleolus. In other cases, forced abduction may produce diastasis of the inferior tibiofibular articulation, or these two lesions may occur together.

These cases are diagnosed by finding acute tenderness and swelling around the tip of the internal malleolus. A sulcus indicating the separation is sometimes palpable. Radiologic examination will disclose any avulsed fragment of bone, and the extent of separation will determine the advisability of operative intervention and repair by suture or screw fixation.

Sometimes the abduction force springs the inferior tibiofibular and interosseous ligaments which bind the tibia and fibula together, and a *diastasis* results. When this occurs clinical examination affords evidence of a severe ankle injury. However, the radiologic report is frequently negative because the bones recoil into position and, unless x-rays are repeated in the position of abduction strain, the diagnosis will be overlooked and a serious disability will ensue (See Plate 91 and Fig. 678).

The student should have in mind the following points to assist in the recognition of these cases:

1. *The clinical picture is that of a severe injury to the ankle. There is gross swelling all around the ankle which appears broader than normal. The patient avoids weight-bearing because of the severity of the pain.*

2. *The point of maximum tenderness is localized on the anterior aspect of the tibiofibular joint just medial to the fibula. There may be a second point of tenderness at the tip of the internal malleolus.*

3. *Radiographs, which on casual inspection may seem negative, on careful study will often reveal a widening of the mortise. This may appear on the medial side in the anteroposterior view. Also, a flake of bone may have been avulsed from the lateral aspect of the tibia. This flake of the tibial tuberosity is often concealed by the fibular shadow but will be perceived on careful examination, if present and suspected.*

The absolute proof of diastasis is obtained by local anesthetic infiltration of the joint, followed by radiologic studies with the foot in forced abduction.

Treatment.—Once the diagnosis is established, two approaches to treatment are possible.

1. *Immobilization in a below-knee plaster cast with the malleolar areas carefully compressed; the foot held at 90-100 degrees.* The cast, which should be changed when the swelling subsides, is maintained for 12 weeks. No weight-bearing through the affected limb should be permitted for at least 6 weeks, but ambulation on crutches is allowed.

2. *Internal fixation by a long screw through the fibula into the tibia.* Plaster immobilization is again required for 12 weeks. The screw must always be removed, as some movement in the tibiofibular joint is essential. This removal may be performed after 6 weeks. In cases where the ligaments have avulsed the tuberosities of the tibia, the healing appears more rapid, and immobilization for 8 weeks is sufficient.

Tendon Lesions

A sudden forced effort of plantar flexion while the foot is supporting the body weight, with or without a superadded load, may cause either a rupture of the plantaris or a rupture of the tendo achillis.

Rupture of the Plantaris

This occurs more frequently in the young athlete at the beginning of a spring, jump, or dive. There is a sudden pain in the calf, a distinct feeling of something giving way, and sometimes an audible snap. The calf becomes swollen, hard, and tender. Walking may be difficult. A "Charley horse" is the

usual lay diagnosis. In the older person a deep phlebitis must be differentiated.

Treatment.—The condition clears in 10-21 days and is assisted by firm elastic bandaging of the limb from the foot to below the knee. A raised heel on the shoe will diminish the tension in the calf when walking and afford considerable relief. Heat, massage, and active exercises will accelerate the recovery after the first 48 hours. There is no contraindication to ambulation or weight-bearing once the discomfort lessens.

Rupture of the Tendo Achillis (Plate 92)

This tendon, which is the strongest in the body, ruptures only on a sudden forcible effort, and only after undergoing degenerative changes due to aging or a specific condition, such as syphilis or gout. The great John Hunter sustained this injury while dancing, and there exists an excellent record of his case with the findings at autopsy years later. Rupture frequently occurs in entertainers who carry on beyond their prime of life.

The history is that of a sudden effort which is accompanied by a snap with pain in the calf, after which the foot becomes useless. Plantar flexion of the foot is impossible.

Examination.—With the patient in the prone position, examination discloses a loss of the normal outline of the Achilles tendon and, with the foot passively dorsiflexed, the sulcus at the site of rupture is palpable. Sometimes the rupture occurs at the musculotendinous junction, and then the diagnosis is more difficult. At other times avulsion of the calcaneal insertion occurs. Typically, however, rupture leaves a part of the tendon attached to the bone.

Treatment.—The ideal treatment is operative suture at the earliest moment, with the site of rupture exposed through a longitudinal incision placed along its lateral border.

The limb is encased, postoperatively, in a below-knee walking cast with the foot at 90-100 degrees. The author does not use the position of plantar flexion to relax the tendon because of the tendency to contracture of the calf muscles.

Plaster fixation is continued for a period of 6 weeks. During this time ambulation is permitted. Following this period, an elastic bandage is employed, and massage and active exercises are used to restore function to the part. Return to violent exercise such as acrobatic work is delayed for 4-6 months. When a shoe is worn, a raised heel, gradually diminished in height over several weeks' time, is advisable.

Recurrent Dislocation of the Peroneal Tendons

The tendons of peroneus longus and brevis pass behind the fibular malleolus in a bony groove of varying depth. Their displacement in the different positions of the foot is prevented by the superior and inferior peroneal retinacula. Stretching or rupture of the superior retinaculum results from a forced eversion while the foot is in plantar flexion.

This rupture permits the peroneal tendons to slip out of the bony groove onto the lateral aspect of the external malleolus. Should the initial lesion remain undiagnosed and untreated, this tendency to recurrent dislocation of the tendons persists as a painful syndrome which occurs on sudden eversion with plantar flexion of the foot.

Treatment.—Primary treatment consists of replacing the tendons and firmly bandaging the foot so as to limit eversion and plantar flexion for 3-4 weeks.

When seen as a recurrent disorder, if the patient's disability is sufficiently severe, a reconstruction of the superior retinaculum, using fascia or a strip of tendon from the peroneus longus or brevis, gives excellent results. Deepening the bony sulcus is usually unnecessary.

Avulsion of the Insertion of Peroneus Brevis

The peroneus brevis is inserted on the prominent tubercle located at the base of the 5th metatarsal. A forcible inversion of the foot against resistance may avulse this tubercle. This injury is often called "dancer's fracture" because of its occurrence while dancing. The diagnosis will be made by the history of a sudden strain, followed by local tenderness with swelling and pain at the base of the 5th metatarsal. Radiologic examination will

Plate 92—Rupture of Achilles Tendon.

Courtesy Moseley, H. F. CIBA
CLINICAL SYMPOSIA 7 167, 1955

demonstrate the fracture and extent of separation.

Treatment.—When displacement is absent, immobilization by strapping suffices. When displacement is present, as indicated by a definite gap shown on the x-ray, a below-knee walking cast for 3-4 weeks gives symptomatic relief and promotes recovery.

Tenosynovitis

Two painful conditions of tendons should be mentioned. They are achillodynia and tenosynovitis of the tibialis anterior. They correspond to a similar disorder of the lower forearm in which the tendons of the abductor pollicis longus and the extensor pollicis brevis cross the radial extensors. The pathologic process is a tenosynovitis produced by such factors as overuse, pressure, or friction.

In *achillodynia*, the synovial membrane, which surrounds the tendo achillis, becomes inflamed. Local tenderness is found on pressure and there is pain with crepitus on dorsal and plantar flexion.

Relief is obtained by elevating the heel of the shoe $\frac{3}{16}$ - $\frac{5}{16}$ " (0.5-0.75 cm). A firm bandage is applied to the ankle and foot over two strips of felt placed one on each side of the tendon. Treatment with hot packs and diathermy is soothing. Counterirritants associated with the administration of salicylates 10 gr. and cortisone derivatives may hasten the recovery.

With *tenosynovitis of the tibialis anterior*, the patient complains of pain on the anterior aspect of the lower third of the leg. Examination will localize the discomfort to the anterior tibial compartment, where the tibialis anterior muscle lies against the anterior border of the tibia. On active dorsiflexion and inversion of the foot, the discomfort is aggravated. A fine crepitus over the tendon is often discernible during these movements.

Treatment.—This consists of firm bandaging of the foot and leg, together with the use of local counterirritants and preparations of cortisone and salicylates.

Fractures and Dislocations of the Ankle

These injuries of the ankle are often grouped together and called Pott's fractures

This corresponds to the designation of fractures and fracture-dislocations of the lower end of the radius as Colles' fractures. It must be remembered that this is a relic of the days before x-rays and that the many varieties of injuries so loosely designated require individual consideration if improvement in standards of treatment is to be obtained.

The classification of ankle injuries follows the writings of Ashhurst, who considered them on a mechanistic basis.

Mechanism of Fractures and Fracture-Dislocations.—The foot may be violently displaced on the leg by the following forces:

1. External rotation
2. Abduction
3. External rotation and abduction combined
4. Adduction
5. Vertical compression

Depending on the intensity and duration of the force, different degrees of fracture and dislocation occur. This is best indicated by diagrams taken from type x-rays, but it must be remembered that all gradations occur. Further, there is frequently an associated compression force when the body weight is transmitted in injuries caused by falls from a height.

Diagnosis.—Fractures without displacement are differentiated from sprains by x-ray examination.

Fractures and dislocations with deformity often present the type appearance expected from the responsible mechanism, e.g., the abducted foot with posterior displacement in the third degree abduction injury. Marked swelling from edema and hematoma may mask the bony landmarks. X-ray examination with anteroposterior, lateral, and sometimes bimalleolar views is required.

Treatment.—

Emergency Measures.—When first seen any gross displacement should be gently corrected to prevent compounding the fracture and to diminish circulatory embarrassment. A firm support for the foot, ankle, and lower leg is arranged, using an Elastocrepe bandage applied over absorbent cotton. A most useful form of splintage is the pillow splint available in any home. This is most satisfactory for transportation to hospital or if the patient must remain at home overnight. The limb is elevated and ice bags are applied. These measures will

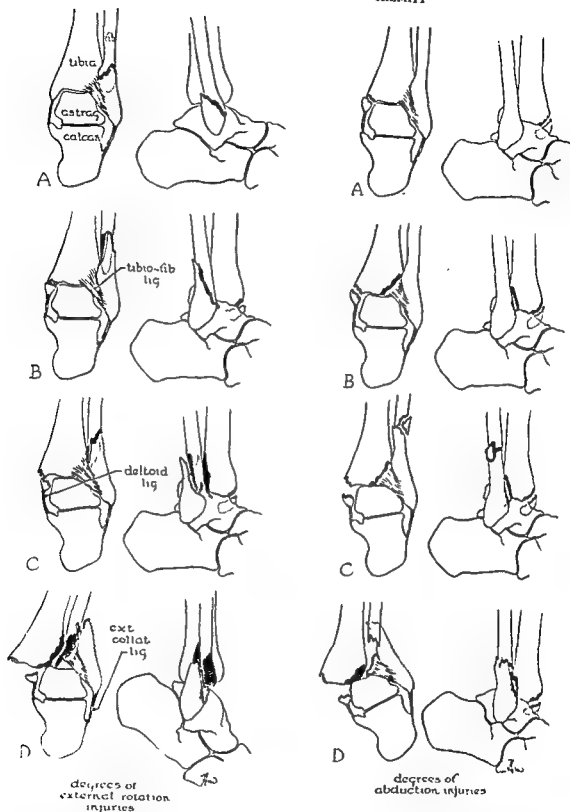

Fig. 677—A, B, C, and D represent stages of severity of the type fractures or fracture dislocations and are often designated first, second, third, and fourth degrees. Needless to say, every gradation exists. The important point is that instability of the mortise occurs from the second degree onward, necessitating most careful plaster splinting, the increasing use of internal fixation, and the avoidance of early weight bearing.

diminish the tendency to swelling which will delay the definitive treatment in these cases. The patient is reassured, and analgesics for pain with sedatives to ensure sleep are arranged.

Principles.—Fractures and fracture-dislocations require exact reduction because this is a weight-bearing joint and the mortise must be

properly restored. In the severe injuries with loss of joint stability, this reduction must be maintained until solid healing has occurred in both bony and ligamentous structures. It is best to avoid weight-bearing for as long as 6 weeks in these severe cases, and plaster casts must be changed as the swelling diminishes and careful molding of the cast around the

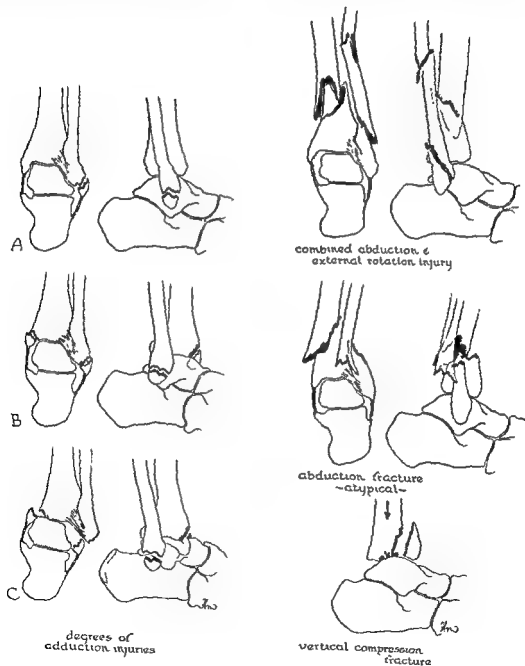

Fig 677, c and d.—Type fractures of ankle

B, Lateral view. Posterior displacement of talus, together with fracture of posterior lip of tibial articular surface

C and D, Result achieved by operative reduction and internal fixation by bolt, washers, and nut

malleoli is required. Movements of all muscles under the cast are encouraged to diminish disuse atrophy. Elevation of the limb to prevent edema is important. When the cast is finally removed, support by Unna's paste bandage or elastic stocking is essential, and this should be combined with physiotherapy.

Reduction.—The earliest possible reduction of all major displacements is required. This is achieved by reversing the mechanism of the injury. Most posterior displacements are reduced by plantar flexing the foot, drawing downward and then forward as the foot is dorsiflexed. Firm compression of the malleoli by the palms of the hands corrects the widened mortise.

90 degrees (100 degrees in female patients with shortened Achilles' tendon), is the standard method. In undisplaced fractures and those without joint instability, immediate ambulation with weight-bearing is desirable.

If marked swelling is present, the application of a cast can be delayed and the edema reduced by elevation and massage. An alternative is to apply a cast for support, elevate the limb, and change in 7-10 days.

In severe fracture-dislocations, a mid-thigh cast with the knee in 20- to 30-degree flexion is applied; the patient is permitted to be ambulatory on crutches, but weight-bearing is avoided for 6 weeks. A change to a walking cast should be made at this time.

Fig. 679—Pillow splint (Gurd's method)

Fracture-separation of the internal malleolus is probably best treated by open operation and internal fixation by screw or suture. This is also true for displaced fractures of the anterior and posterior tibial articular margins. In the latter, the so-called posterior malleolus, the fracture line after manipulative reduction often persists as a "step" on the weight-bearing surface. Open operative correction is essential in these cases to prevent the development of traumatic arthritis. This is especially true if the fragment constitutes one third or more of the articular surface.

Fixation.—In those cases with a stable ankle mortise, a below-knee cast, with the foot at

Minor fractures require immobilization for 3-4 weeks. Major injuries may require plaster fixation for 8-12 weeks.

Most patients require re-education of the limb musculature and arch support on removal of the cast.

Complications.—

- 1 Traumatic arthritis
- 2 Post-traumatic edema with thickening of the cast
- 3 Recurrent dislocation of the ankle
- 4 Recurrent dislocation of peroneal tendons
- 5 Nonunion of internal malleolar fractures
- 6 Widening of mortise with inferior tibio-fibular diastasis

Calcaneus

Calcaneal fractures constitute the most disabling group of traumatic disorders involving the tarsal bones. The crush type fractures result in prolonged periods of disability, and Creer reports 20% incapacitated for work 3 years after the accident and still totally incapacitated at 7 years. Although fracture of the femoral neck is still regarded as the "unsolved fracture," the author would transfer the focus of attention to the crush fractures of the calcaneus. Understanding of the problems concerned and improvement in the functional recovery are evolving from attempts to analyze the individual types of fracture and the end results achieved by the different methods of treatment applied to the particular pattern of injury. Little progress could be expected while all types of fracture were treated by a routine approach and the end results recorded without correlation as to the type of fracture in question.

Mechanism of Injury.—The usual mechanism is a fall of varying distance onto a surface of varying consistency. Other variable factors are the patient's age, weight, and occupation. As can be readily understood the extent of calcaneal damage will vary considerably. The force may be distributed between the two feet, resulting in bilateral fractures of different degrees. Calcaneal fractures due to falls from heights are associated with compression fractures of the dorsolumbar vertebral bodies in approximately 10% of cases. Isolated fractures may be caused by direct violence or avulsion.

Classification —

Isolated Fractures —

Beak fracture above tendo achillis insertion

Fracture of sustentaculum tali by direct violence

Vertical fracture of medial tubercle by avulsion or direct violence

Fracture into calcaneocuboid joint by forced inversion

Crush Fractures —

Not involving subtalar joint

Involving subtalar joint

(1) Joint depression type

(2) Tongue fracture type

Clinical Picture.—The patient gives a history of a fall or direct violence to the heel with pain and inability to bear weight on this part.

Examination shows swelling due to edema and hemorrhage. There is acute tenderness on compression.

X-rays should be taken in the standard anteroposterior and lateral planes to include the ankle. Special axial views are required to demonstrate details of the type of fracture.

In the lateral x-ray, the tuber-joint angle should be estimated to see the degree of upward displacement of the posterior fragments. Attention should also be devoted to the degree of involvement of the subastragloid and midtarsal joints.

Fractures of the os calcis may be bilateral and are often associated with compression fractures of the dorsolumbar spine. Examination for this related injury should never be omitted.

Treatment.—The calcaneus is largely composed of an internal structure of cancellous bone with an outer cortical layer whose thickness varies in different parts. This shell, when grossly comminuted, is very much like the problem of Humpty Dumpty. Furthermore, the articular surfaces for the talus are usually deranged in the crush fractures so that a painful post-traumatic arthritis is a frequent sequel. Like cancellous bone elsewhere, e.g., vertebral bodies, a period of 3-4 months is required for healing, and compression by weight-bearing must be avoided to prevent deformity. The routine of incorporating the leg and foot of these patients in plaster casts with or without incorporated spikes or pins for 10-12 weeks is not without complications. Post-traumatic bone atrophy with osteoporosis, circulatory imbalance, atrophy of articular cartilage, and joint stiffness is the all too frequent complication. This is especially true for patients over 50 years of age. As a result of this fact many specialists are tending to treat calcaneal fractures of all patients over 50 as soft part injuries. This treatment includes elevation, protection from weight-bearing, compression bandages, and early massage and movements of all the joints of the ankle and foot. This method is also employed for most

of the isolated fractures except those requiring open operation and internal fixation.

Radical measures are being restricted for the groups with an altered angle of incidence and those involving the subtalar joint in patients under 50 years of age, and this residue comprises 35-40% of any large series of cases.

Palmer and Essex-Lopresti distinguished two types of fracture involving the subtalar joint:

1. Joint depression type
2. Tongue fracture type

These are the two types of calcaneal fractures which so frequently result in total disability. The joint depression type is the more

to work within one year, which is a great advance. An alternate therapy is the use of subtalar or triple arthrodesis in these crush fractures performed 3-6 weeks after the initial injury. Salvage of some of the poor results of crush fractures is also possible, with similar arthrodeses performed 18 months or more after the initial injury. Although there is a definite tendency for continual improvement up to 3 or more years, the average case is stabilized and the result obtained within this period of 18 months.

Complications.—

1. Traumatic arthritis of the subtalar joint. This gives pain when walking, especially on

Fig 680—External skeletal fixation for fractured calcaneus

common, and in these cases the whole segment of the posterior joint surface is driven downward and backward. Open operative reduction and fixation by packing the resultant cavity beneath the articular surface with cancellous bone (Palmer) or retention by spike incorporated in plaster (Essex-Lopresti) are being used in these cases with some improvement in the results. In the tongue fracture type reduction by Bohler's two-pin method or Gissane's spike would appear to offer the best solution.

Series of these serious types are being reported, with 80% of the patients returning

irregular ground. If severe, arthrodesis is indicated.

2 Widening of the bone, causing impingement on the lateral malleolus. If symptoms are severe, arthrodesis of the ankle and subtalar joints is required.

3 Upward displacement of the posterior fragments resulting in relative elongation of the tendo achillis. Alteration in the appearance of the calf and ankle will be present with increased range of dorsiflexion.

4 Bony prominences in the sole of the foot which give pain from pressure.

Tarsus

The *talus* is the keystone of the longitudinal arch and constitutes the connecting bone between the leg and foot. Injuries of this bone are uncommon, but because of its essential function, the most efficient treatment is required to secure good results.

Classification.—Watson-Jones has classified injuries of this bone on the basis of the causative mechanism:

1. Inversion injuries*
 - a. Dislocation of the ankle
 - b. Subtalar dislocation
 - c. Total dislocation of the talus
2. Dorsiflexion injuries
 - a. Fracture of the neck of the talus without displacement
 - b. Fracture of the neck with subtalar dislocation
 - c. Fracture of the neck with subtalar dislocation and backward displacement of the body
3. Adduction and abduction injuries of the forefoot
 - a. Midtarsal dislocation with fracture of navicular
 - b. Tarsometatarsal dislocation with fracture of metatarsals

Diagnosis.—In cases of complete dislocation of the talus, diagnosis is easily made. The injury may be compound. Other cases present typical deformities. The exact post-traumatic anatomy is best assessed by careful x-ray examination.

Treatment.—Reduction should be carried out at the earliest moment. In complete dislocation of the talus, especially if compound, open operative reduction is best. The bone should not be removed even if devoid of ligamentous attachments. In dorsiflexion injuries, the ankle must be fixed in full plantar flexion to maintain reduction.

In severe injuries and dislocations, weight-bearing should be avoided, although the patient can be ambulatory on crutches. When aseptic necrosis of the talus is expected, weight-bearing is contraindicated for 4-6 months. The usual case may gradually increase weight-

bearing after 6 weeks. A below-knee cast gives adequate protection.

Other Tarsal Injuries

Direct violence may cause isolated fractures of other tarsal bones, of which the navicular is most commonly involved.

Treatment must be carried out to secure union in satisfactory position, and every effort is directed to preserve the arches of the foot and the muscular balance.

Metatarsal Fractures

The five metatarsals may be fractured at any point in their length. Fractures involving the base of the 5th and necks of the 2nd and 3rd metatarsals are most common.

Base of Fifth Metatarsal

Fracture in this situation is often called "dancer's fracture." The attachment of peroneus brevis is avulsed in sudden inversion of the forefoot. The base may also be fractured by direct violence. Strapping or plaster cast immobilization for 10-21 days suffices.

Shafts of Metatarsals

The shafts may be fractured obliquely by indirect torsion or transversely by direct violence.

Treatment.—If displacement is minimal, a walking cast, with sponge rubber molded to preserve the long arch and concavity of the foot, will prove satisfactory. Crutches should be used for 10-14 days. The cast is required for 4-6 weeks.

If displaced, traction through the corresponding phalanges should secure reduction. Care must be taken to avoid angulation into the sole of the foot. A metatarsal bar will be helpful when walking begins.

Necks of Metatarsals

The neck of metatarsal 2 or 3 may fracture from the stress of forced walking. This has been termed "march fracture."

Care must be taken to prevent excessive callus formation, which will give prolonged

CLINICAL SYMPOSIA 7: 167, 1955

sability. This is obviated by early recognition and avoidance of unprotected weight-bearing; using a walking cast and crutches for the first 10-14 days.

Fractured Phalanges

Crushing injuries of the great toe are the most common. These result from direct injury from falling objects such as carried cases, furniture, etc. or by stubbing the toe. The injury is often compound.

Treatment consists of careful cleansing of the part, evacuation of subungual hematoma, and application of an easily removed splint. Elevation and hot baths when the wounds have closed diminish the swelling.

Ambulation should begin with crutches. A metatarsal bar is applied to the shoe, which has been cut out over the dorsum of the affected toe.

Dislocations of the Toes

Dorsal dislocation at the first metatarsophalangeal joint is the common dislocation. It is readily reduced by traction in flexion, with direct pressure. The reduction is stable, and protection from the pressure of weight-bearing is the essential point in treatment. The time required is determined by the disappearance of pain and tenderness. Crutches for 2-3 weeks are the usual requirement. A metatarsal bar should be applied to the shoe.

STATIC DISORDERS OF THE ANKLE AND FOOT

Posture of the Normal Foot

(Plate 97)

The long axis of the foot may be directed inward (in-toeing) up to 15 degrees or outward (out-toeing) up to 25 degrees, or forced up to 90 degrees, and the apparent average posture when standing is a position of out-toeing of 15 degrees. This angle is greatest when a person is stationary, less when walking, and least when running.

The direction of the long axis of the normally postured foot is determined by the rotation of the lower limb at the hip since the talus is firmly held in the ankle mortise. Thus

out-toeing presupposes external rotation and in-toeing, internal rotation at the hip joint. This interrelationship is important in our clinical examination when the foot presents the common static disorder of valgus deformity, and the direction of the patella is taken as our indicator of lower limb rotation.

Distribution of Body Weight

The body weight is transferred through the legs to the two feet, each foot receiving one-half the load. Measurements have shown that the weight is equally divided between the hind-foot and the forefoot as to a tripod. Analysis of the distribution through the forefoot discloses that the two sesamoids under the head of the 1st metatarsal and the heads of the 2nd, 3rd, 4th, and 5th metatarsals each receives an equal share. In this way the ball of the great toe sustains twice the pressure of that under each lateral metatarsal head. This ratio of weight borne by the hindfoot and forefoot is true only for the bare foot, and naturally in shoes the proportion carried by the forefoot increases as the level of the heel is raised.

When standing stationary, the *axis of balance* passes through the center of the heel and forward between the 2nd and 3rd metatarsals. When walking or running, the weight is transferred more medially and the *axis of leverage or propulsion* runs between the 1st and 2nd metatarsals.

Evolution of the Normal Foot

The human foot is a wonderful mechanism evolved in structure and function for stability and locomotion, our understanding of which can be greatly assisted by a brief reference to comparative anatomy.

When we compare the human foot with that of the anthropoid, we note that the human being has largely ceased to employ the foot for grasp, whereas the arboreal life necessitates brachiation. As a result, in the anthropoid, the 1st metatarsal segment is in varus and short, and its associated prehensile hallux is also short and mobile. In comparison, marked changes have occurred in the human foot. The varus position of the 1st metatarsal segment has largely disappeared. The great toe and its metatarsal have increased greatly in size and

become aligned in the long axis of the foot. With this change a great deal of the mobility has been lost, with consequent increase of the stability required for propulsion. The metatarsophalangeal joint of the 1st digit is now situated just distal to that of the 2nd digit.

Further changes include the great increase in the proportion of the tarsal segment, the proportion of the lateral four metatarsals remaining approximately constant while the lateral digital elements have been greatly reduced. The tarsal segment has lost mobility and has become more stable due to the altered structural arrangements of the bones and ligaments at the expense of the intrinsic musculature. The heel has been brought to the ground and an inner longitudinal arch formed to give elasticity to the gait.

The balance of the normal human foot therefore depends on two main factors: (1) the *structural stability* determined by the mechanical arrangements of the component bones and their articulations and associated ligaments and (b) the *postural stability* maintained by the activity of the intrinsic and extrinsic musculature.

Theories on Instability of the Foot (Plates 98 and 99)

Since the stability of the foot depends on the mechanical arrangement of its components and the balanced activity of its musculature, the explanation of static disorders will be found in derangements in these two aspects of the problem. However, with the tendency of the human mind to simplify, there have been two schools of thought, the one trying to explain most disorders by muscular imbalance, the other by structural defects. To the author it would seem that there has tended to be a fixation of thought on muscular imbalance rather like that found in the clouding of understanding of low back disorders by terms such as lumbago and sciatica and of shoulder disorders by terms like bursitis and neuritis. Just as the work of Schmorl on the intervertebral disc and that of Codman and Meyer on the supraspinatus and biceps tendons have brought light to these subjects, so the work of Dudley J. Morton, R. I. Harris, and many others is bringing understanding to the

subject at present under discussion. The search for an underlying demonstrable organic and structural basis for each type of foot disorder will be found to be the key to further advance in our comprehension. It is true that in certain cases of pes valgus the problem is that of muscular insufficiency as present in the overweight individual and in the patient after bed confinement or after plaster immobilization for injury, but by and large it will be found most helpful to regard the muscular imbalance as secondary to structural defect.

Structural Variations of the Human Foot

Probably one of the characteristics of the foot which most confuses the physician when evaluating its disorders is the variability of its size, shape, and functional qualities as noted in different individuals. Even its changes from birth to old age in the same person constitute a clinical study in themselves. In this connection certain points should be mentioned. The shape and size of the foot will tend to vary with the bodily habitus. A long narrow foot will be found in the tall thin man, whereas a shorter, broader foot will be present in the thick-set type. Yet every gradation of shape and size will be found in any general survey of patients.

In addition to this generalization on the structural variations, however, the student should look for the type of foot which occurs in approximately one third of the population, so well described by Dudley J. Morton, and which follows from the above remarks on the comparative anatomy of the foot taken largely from his writings. This investigation has stressed the structural type with the short, hypermobile, and often varus 1st metatarsal segment, associated with a short great toe and proximally placed metatarsophalangeal joint which might be regarded as an evolutionary throwback to more primitive ancestors. These cases present a structural defect which gives a lack of stability of the great toe element in propulsion and stance, with the result that the relatively longer 2nd metatarsal takes a disproportionate load. In time and with excessive use, *accentuated in the female sex by the wearing of high heels*, there is a hyper-

trophy of the 2nd metatarsal shaft, indicated by a widening of the bone and thickening of its cortex, an excessive strain on its articulation with the middle cuneiform causing synovitis followed by traumatic arthritis, and often premature degeneration of its articulation with the phalanx (Freiberg's disease). Calluses appear from the excessive intermittent pressure under the 2nd and often the 3rd metatarsal heads and, in the female sex, this is probably the most common static derangement of the forefoot. The excessive mobility of the 1st metatarsal segment and the distribution of weight largely through the 2nd and 3rd segments causes the foot to assume a valgus position, with muscular imbalance a secondary factor.

Following this trend of thought, a further addition to our understanding has come from the investigations of Harris and Beath. A foot survey was made of 3,619 Canadian recruits for World War II. All were males 18-35 years of age. In this investigation special attention was directed to the valgus foot, and they found that the most disabling type was that which they have designated "*the hypermobile flatfoot with short tendo achillis*." This disorder they believe is due to a lack of adequate calcaneal support for the head of the talus. This structural tarsal defect is associated with a shortened tendo achillis.

The clinical history of such cases reveals a foot disability of varying severity commencing in childhood. On examination one notes that on weight-bearing the foot assumes the valgus position of the heel and forefoot, whereas the shape and arch of the foot reform when the body weight is removed. If, with the knees held fully extended, the movement of the foot from plantar to dorsal flexion is tested, it is found that marked restriction in this movement at the ankle is present, stopping usually at 105 degrees and rarely reaching the right angle. However, at the point where ankle movement ceases, hypermobility and instability at the subtalar and midtarsal joints are noted, and further movement into dorsal flexion occurs as the whole foot moves into valgus around the talus. This type of pes valgus constituted 6% of the disabling disorders of the foot in their survey.

The second group presenting serious disability were those included in the designation "*peroneal spastic (rigid) flatfoot*" which accounted for 2%. These cases give a history dating back to adolescence, and in time secondary structural changes produced a rigid valgus foot incapable of sustaining prolonged use. In this type of pes valgus the deformity is largely at the subtalar joint.

Their original investigations have been continued, and they find that a certain percentage of these cases present congenital structural tarsal anomalies.

The first of these defects is the *calcaneotalar bridge* which may be osseous, cartilaginous, or fibrous and unites the posterior aspect of the sustentaculum tali with the talus. This abnormality, first noted at operation, interferes with the normal motion in the subtalar joint and results in an increasing valgus deformity of the heel and a secondary valgus or pronation deformity of the forefoot occurring at the midtarsal joint. In time, degeneration, as disclosed by osteophytic lipping, occurs in the talonavicular joint. The lateral x-ray of the tarsus disclosing this change should suggest the posterior oblique view of the tarsus, which will often reveal the full-blown osseous bridge. It is possible that some cases of talipes calcaneovalgus may be due to this structural defect.

A second abnormality, the *calcaneonavicular bar*, may be found on oblique lateral views of the foot. Again it may be osseous, cartilaginous, or fibrous in nature and in certain cases will lead to a rigid valgus foot presenting for diagnosis and treatment because of pain and deformity.

Accessory Navicular.—One further structural anomaly should be mentioned. An accessory navicular bone is present in 5% of people. It causes an undue prominence on the medial side of the foot and is often referred to as an accessory or secondary medial malleolus. Sometimes it is fused and the prominence is that of an abnormally large tuberosity of the navicular. Its clinical importance is that it is sometimes associated with intractable painful valgus feet in adolescents and also that its undue prominence subjects it to excessive friction and pressure.

These five groups of structural anomalies should be differentiated in cases presenting for examination for the so-called fallen or flattened longitudinal and metatarsal arches. In such cases muscular imbalance appears to be secondary to the structural abnormality.

Nomenclature (Plate 100)

Further discussion will be more readily followed if we now clearly define the various terms in common use.

The generic term *talipes* used in describing the deformities involving the ankle and foot is derived from the Latin words *talus* meaning ankle or ankle bone and *pes* meaning foot. Thus *talipes* should be used when the deformity involves both the ankle and foot, while *pes* is the generic term to be employed when the disorder is limited to the foot alone.

Movements at the ankle joint are chiefly plantar flexion and dorsiflexion. Because through evolution the horse has a foot in marked plantar flexion, the comparative anatomist has given the human foot deformity characterized by plantar flexion the name *equinus* (from *L. equus*, horse). The reverse deformity, characterized by dorsiflexion of the foot and prominence of the heel, is designated *calcaneus*.

The terminology of deformities involving the foot proper is best understood by considering the movements of the remainder of the tarsus and metatarsus as a unit in relation to the talus. A movement of this unit into inversion and adduction (supination) draws the foot toward the midline of the body, which is termed *varus* (*L.*, bent inward), whereas the opposite movement into eversion and abduction (pronation) results in a *valgus* (*L.*, bent outward) deformity.

When the foot is in *valgus* position, the longitudinal arch appears flattened and is often referred to as *flatfoot*, *pes planus*, or *pes valgus*. On the other hand, a *varus* deformity with an exaggerated depression (*equinus*) of the metatarsals increases the concavity of the arch and is termed *pes cavus*.

Combined deformities at the superior, inferior, and anterior articulations of the talus, i.e., of the ankle and foot, are best seen in

the types of congenital clubfoot and can be classified as follows:

Talipes	{ equino	{ varus
		{ valgus
{ calcaneo	{ valgus	{ varus
		{ valgus

The significance of these terms will be more clearly understood as the various disorders are described in greater detail.

Examination

A careful history of the patient's complaints should be taken. General factors such as occupation, the necessity for prolonged standing or walking, carrying heavy weights, exposure to cold or wet environment, and, in the female patient especially, the type of footwear should be noted. Vascular problems demonstrable as ankle edema, varicose veins and their sequelae, and arterial insufficiency are important. The duration and degree of a diabetic derangement require accurate investigation.

The patient should be examined standing and walking with and without shoes, with limbs exposed from the lower thigh down. Deformity such as the valgus heel and forefoot is readily seen. On removal of the shoes and socks, the physician will quickly learn the patient's *care of his feet*. The *nails* will be noted as to method of pedicure, the presence of nutritional changes, ingrowth, deformity, or infection. The *clefts of the toes and soles* will be examined for fungous infection, plantar warts, or other dermatologic disorder. The position of corns and calluses indicates the *pressure points*. If foot-printing facilities are available, such provide valuable records of the shape and pressure points. The same information can be gained by noting the *texture of the skin*, whether soft or calloused, over the pressure areas. Manipulation of the foot will reveal the *mobility of its different parts*. In the peroneal spastic valgus foot, movement into inversion will initiate the spasm, and the rigidity of the valgus deformity will be appreciated. The *pulsations of the dorsalis pedis and posterior tibial arteries* should always be recorded, as also any *neurologic deficit* whether sensory or motor. With experience the student will learn to correlate the clinical history.

CLINICAL SYMPOSIA 9: 83, 1937.

symptoms, and signs in relation to the particular disorder presented by the patient.

Congenital Anomalies

The development of the ankle and foot may be arrested at any stage, and thus a multitude of variants occurs. Talipes, or clubfoot, and congenital structural anomalies already described are the most frequently encountered.

Congenital Talipes Equinovarus (Plate 101)

The word *talipes* is derived from the Latin words, *talus* and *pes*, and is the term used to cover all deformities of the foot centered on the talus. Congenital talipes equinovarus, or clubfoot, is the commonest congenital deformity. It may be unilateral or bilateral, it may occur as the only congenital abnormality or be associated with other stigmas such as cleft palate, *spina bifida*, *arthrogryphosis multi-*

plex, etc. There is a tendency for this defect to run in families.

Classification.—

SIMPLE TYPES

Talipes { equinus
 { calcaneus

Pes { varus
 { valgus

COMBINED TYPES

Talipes { equino { varus
 { valgus
 { calcaneo { varus
 { valgus

Etiology.—Various theories as to the causation of this deformity have been postulated. The view most commonly held is that it is due to the persistence of the feet in the plantar flexed and adducted position which is normally present up to the 3rd month of intrauterine life. In recent years experimental work on developing embryos of various animals and birds suggests that congenital defects are developmental arrests which may be due to chemical changes in the fetal environment during the "critical phase" of development. The work of Duraiswami is most interesting in

Fig. 681.—Multiple congenital deformities of the lower limbs. On the right side, a talipes equinovarus is present together with failure in the differentiation of the great, second, and third toes. On the left side, there is a congenital constricting band just below the knee. The leg below this is of increased size, and there is a failure of differentiation of the toes.

this respect; he has been able to produce most of the typical congenital deformities in chickens by injecting various doses of insulin into the yolk of fertilized eggs. The critical phase of development is different for the various parts of the body. Thus, injection during the first 2 days of incubation caused defects in the vertebral column, on the 3rd day deformities of the feet, and on the 4th and 5th days deformities of the limbs and beak. A further interesting point shown in this research was that once the tendency to deformity had been induced, the deformities recurred in the next generation. From this research it would appear that dietary and hormonal influences during pregnancy may be the causative factors.

Pathologic Anatomy.—Analysis of the deformity shows that it consists of several parts (Plate 101):

1. The foot is plantar flexed. This equinus position takes place at the ankle joint where the talus is angulated plantarward and also at the midtarsal joint where the forefoot is angulated plantarward.

- 2 The varus deformity occurs mainly at the subtalar joint

- 3 An adduction deformity which is chiefly at the midtarsal joint, which draws the forefoot medially. In the infant this deformity is plastic, but as months and years pass, structural changes increase with alteration in the shapes of the bones, in the structure of the ligaments to fix the deformity, and with contractures of the muscles in the position of imbalance. Walking tends to aggravate the deformity. Pressure points occur from shoes and where weight-bearing is most marked. In the severe case the patient walks on the outer border of the foot

Diagnosis.—The clinical picture is so typical that the deformity is usually noted by the medical attendants at birth. When found, the presence of other defects should be suspected. The possibility of a nerve lesion associated with a spina bifida and paralytic type of talipes must be excluded.

Treatment.—The essential points in treatment consist of the earliest possible diagnosis and the immediate institution of corrective

measures. Some orthopedists begin treatment at birth; others wait until the child can be brought for treatment.

At this stage the dynamic splinting devised by Denis Browne is used. The feet are fixed on foot plates which are then attached to a crossbar which maintains external rotation and valgus. The movements of the limb stretch the shortened tissues while developing the muscle power. Full correction is obtained within a few weeks, but splinting is continued in order to prevent recurrence. When the child commences walking, outside wedges are used on the shoes. A similar type of night splint is applied when the child is resting. Clinical review of progress is continued at intervals until the age of 12 years.

The method of dynamic splinting has replaced repeated manipulation and plaster casts to hold correction which were previously in use.

In those patients who have not received the benefit of early diagnosis and treatment, and who present after the age of 2 years, repeated manipulation and plaster fixation can be employed. It is essential to avoid the use of excessive force. With repeated manipulations at intervals of 3 weeks and plaster fixation, resistant cases can be corrected, utilizing the plasticity secured by the osteoporosis of disuse.

In certain of these cases there is a fixed equinus deformity which requires correction by posterior capsulotomy of the ankle joint associated with elongation of tendo achillis by Z-plasty from the medial to lateral side. A further group will require a tibialis anticus transplant to the lateral side of the foot to correct the metatarsus varus deformity. This is usually carried out at 5-10 years of age.

After 11-12 years of age, cases presenting appreciable residual deformities are corrected by triple arthrodesis with suitable wedge resections.

Pes Cavus

This is one of the most disabling deformities of the foot. It is characterized by exaggeration of the long arch. The metatarsal heads, especially the 1st, are drawn proximally and project below the level of the calcaneus. The toes are clawed. In time, contracture of all the

Fig. 682—Twins presenting a marked degree of bilateral equinovarus, showing the result achieved after orthopedic treatment

Fig. 683—The Denis Browne dynamic splinting used on a case of clubfeet. Each foot is first carefully bandaged to a well padded metal plate and is then fixed, as illustrated, to a metal crossbar. The crossbar is bent so as to secure a valgus position of the foot, and the plate is fixed in external rotation. In this way the kicking movements stretch the shortened soft tissues while developing muscular power.

soft tissues occurs, and there is a shortening of the tendo achillis, giving an added equinus deformity.

The deformity can be analyzed into the following components:

1. Inversion at the subtalar joint
2. Possibly a calcaneus deformity
3. Dropping of forefoot (equinus) at mid-tarsal joint level

4. Possibly clawing of all toes

There are various etiologic factors resulting in this deformity:

1. Upper motor neuron lesion, e.g., Friedreich's ataxia
2. Lower motor neuron lesion, e.g., poliomyelitis
3. Congenital defects associated with spina bifida and cauda equina lesions

4. Muscular dystrophy of peroneal type

5. Vascular ischemia, e.g., following fractures of the upper end of tibia, giving Volkmann's type of contracture

The above group accounts for only about 20% of cases. The vast majority are of unknown cause and are classified as idiopathic.

Clinical Picture.—The patient may present any degree of severity of the deformity. In the young, considerable mobility may still persist, but, with years, fixed deformity of the bones and joints occurs, with marked soft tissue contractures. The metatarsophalangeal joints may be dorsally dislocated. Severe, painful, and disabling calluses may be present.

Treatment.—Therapeutic measures will be determined by the patient's age, the severity of the deformity and disability, and the underlying mechanism.

Conservative measures include the use of special orthopedic shoes, manipulation, wrenching, splinting, and physiotherapy. *Radical treatment* includes section and advancement of the plantar soft tissues from the calcaneus to the plantar (Steindler), capsulotomies of the metatarsophalangeal joints with flexor-extensor transplants or arthrodesis of all interphalangeal joints to correct the clawing of the toes, wedge tarsectomies in late cases and even below-knee amputations may be required.

Some Remarks on Flatfoot

It is probable that the concept of flattened arches has done more to confuse the diagnosis

and treatment of static disorders of the foot than anything else. For this reason this exposition has stressed the structural variations of the foot and the delineation of the clinical entities that are readily demonstrable by the practitioner.

Many individuals have a foot of normal structure, but presenting a low arch, which is completely adequate for their work load. It is only when function is impaired and symptoms develop that a clinical problem arises. This may be in the way of acute or chronic foot strain from excessive use. *Acute foot strain* was occasionally seen in the days before the early ambulatory treatment of the hospitalized medical or surgical patient. After prolonged confinement to bed, muscular insufficiency was present, and ligamentous strain gave rise to pain and disability. Such is also noted after prolonged plaster immobilization of the lower limb for traumatic or orthopedic disabilities, after rapid gain of weight, and when the patient is subjected to unaccustomed prolonged standing, walking, or carrying of heavy loads. The treatment of such disorder of the foot must be directed to rest from the unaccustomed weight load and to graduated development of muscular strength by active resistance exercises.

Similarly, certain normal feet may become involved due to systemic disease such as gonorrhea, rheumatoid arthritis, and specific fevers. Some cases of peroneal spastic flatfoot may result from tarsal arthritis due to an infective agent. Such problems must be dealt with on the basis of the systemic disease and the foot protected during its activity.

Apart from the above situations one should concentrate on recognizing the syndromes with definite structural anomalies, which have been carefully delineated above.

Treatment of Hypermobile Flatfoot with Shortened Tendo Achillis.—The clinical features of this disorder together with the variability of its severity as to deformity and symptoms have been previously mentioned.

The treatment will be determined by the age of the patient and the severity of the clinical symptoms. Harris recommends conservative measures for all patients up to late adolescence or young adult life. *Palliative therapy* includes raising the heel of the shoe or boot, additional

inside wedges to the heels and soles, Whitman's plates, and exercises. *Operative procedures* should be restricted to the severe cases and should not be performed before the age of 12 years. Arthrodesis of the talonavicular and subtalar joints through a medial incision is recommended.

Treatment of Peroneal Spastic (Rigid) Flatfoot.—Here again the changing concepts of the underlying mechanisms of this group of disorders will tend to modify the principles of treatment. We have seen that some of these cases presumably have an infective basis. Such patients are best treated by manipulative correction, under anesthesia if necessary, and

ence on will be found necessary. Resection of the bar and subtalar and talonavicular fusion with correction of the deformity are advocated.

Similarly, in the problem of the talocalcaneal bridge with severe symptoms, fusion of the talonavicular joint and the subtalar joint when the osseous bridge is incomplete should afford the best solution.

Disorders of the Hindfoot (Plate 102)

Pain in the Region of the Heel

Lesions of the Calcaneus.—This bone is subject to the various disorders affecting any

Fig. 684—Hypermobile flatfeet with short tendo achillis

rest in plaster in the corrected position for 6-8 weeks. If on removal of the cast the spasm of the peroneals and extensors returns, a further period in the cast should be tried. The patient is ambulatory on crutches but without weight-bearing.

In cases presenting the calcaneonavicular bar the severity of the symptoms and signs is also variable. Some patients with complete osseous bar are without symptoms. When the symptoms are severe and conservative measures have failed, operative measures from late adoles-

cence on will be found necessary. Resection of the bar and subtalar and talonavicular fusion with correction of the deformity are advocated.

Similarly, in the problem of the talocalcaneal bridge with severe symptoms, fusion of the talonavicular joint and the subtalar joint when the osseous bridge is incomplete should afford the best solution.

Apophysitis (Osgood's or Sever's Disease).—Osteochondritis affecting the epiphysis

of the calcaneus occurs in children in the age range 8-15 years. There is complaint of pain in the posterior part of the heel which may have followed a strain or blow. The discomfort runs a self-limiting course of 3-6 months.

The posterior surface of the calcaneus is tender and slightly swollen on examination. Radiology discloses the epiphysis to be of increased density, with appearance of fragmentation as seen in Perthes' disease of the hip.

Treatment consists of raising the heel of the shoe $\frac{3}{16}$ " If this does not suffice to relieve the discomfort, the foot is placed in 10- to 20-degree equinus in a below-knee walking cast for 4-6 weeks.

Subcutaneous Bursitis.—The friction and intermittent pressure of the shoe may irritate the subcutaneous bursa over the posterior prominence of the heel.

In the acute stage protection from friction is required. In the presence of infection, hot bathing, surgical dressing, and sometimes antibiotics are indicated. Recurrence is prevented by properly fitted shoes with a heel protector.

Retrocaneal Bursitis (Haglund's Disease).—In certain patients there is a prominence of the posterolateral angle of the calcaneus. This is especially well seen on dorsiflexion of the foot, and the soft tissues over the prominence may be reddened and the related bursa inflamed. Radiologic examination does not usually disclose any marked bony projection.

Treatment necessitates protection by heel pads. If the condition becomes a nuisance, resection of the underlying bony prominence can be performed.

Achillodynia (Tenosynovitis of the Achilles Tendon).—Inflammation of the synovial-like tissue around the tendo achillis frequently results from overuse or may be of a rheumatic or gouty nature (See page 1187).

Plantar Fasciitis (Calcaneal Spur).—Discomfort, tenderness on pressure, and pain on walking related to the anteromedial and middle-plantar aspects of the calcaneus in the middle-aged male patient constitute a common dis-

order. It is most frequently seen in overweight men with tendency to gout, osteoarthritis, and degenerative vascular disease. The onset may follow a bruise of the heel but is usually insidious and without known cause. The patient may find it almost unbearable to place the weight through the foot in the morning on rising and will massage the heel before attempting to do so.

Clinical examination localizes the tenderness at the attachment of the plantar fascia, especially on the medial side. In more severe cases the whole calcaneus and subtalar joint areas may be tender on pressure.

A lateral x-ray film may show a large spur and sometimes a calcified deposit as seen in the shoulder and elbow areas.

Treatment.—The disorder may respond rapidly to protection by wearing a heavy wool sock, applying a rubber pad with a hole cut out over the tender point, and using rubber heels on the shoes. In more refractory cases, deep kneading massage, diathermy, or ultrasonic therapy may help. Injection of procaine and hydrocortisone (25 mg) has sometimes produced dramatic results. Meticorten and salicylates by mouth have been the most useful drugs.

The symptoms and signs in no way appear to be related to the size of the bony spur, and removal of the spur should rarely be advised. Relief from such procedures probably results from section of the plantar fascia and the resulting hyperemic reaction.

Köhler's Disease of the Tarsal Navicular

Pain and tenderness on the medial side of the foot is found in children in the age range of 8-15 years. This is due to an osteochondritic process involving the navicular bone. The area may be tender on pressure, and radiologic examination discloses the typical changes of increased density with areas of rarefaction to which the descriptive term *fragmentation* is given. The bone appears narrower than the normal as seen in the x-ray of the opposite foot.

The process runs a self-limited course and treatment is rarely required. A period in a plaster cast may be arranged if the complaint of pain is marked.

Plate 103.—Hammertoe, Bunionette, Morton's Toe.

Disorders of the Forefoot

Metatarsalgia (Fallen Metatarsal Arch)

Flattening of the transverse arch at the level of the ball of the foot, with resultant pain, designated *metatarsalgia*, is the most common complaint in the middle-aged female patient. Morton's explanation of this syndrome has already been given. Others explain the causation as follows.

Normally the muscular balance of the foot arranges that the weight is carried from the heel to the outer border of the foot, thence to

The patient complains of the increasing pain in the forefoot, often localized to the area of the callus, but frequently radiating up the muscles of the leg. The metatarsalgia is aggravated by wearing shoes, and the complaints are of increasing difficulty in securing a satisfactory fitting.

Treatment is directed to minimizing weight-bearing in shoes during the acute phase. A metatarsal pad is placed behind the metatarsal heads, with elastic strapping of the forefoot, or Morton's compensating insole is prescribed. The patient is given faradic foot baths

Fig 685—X-ray of Kohler's disease of left navicular with normal right navicular for comparison

the ball of the great toe, propulsion forward then being given by the plantar flexion of the proximal phalanx of the hallux. In dysfunction of the interosseous and lumbrical muscles the forefoot splays and the proximal phalanges of the four lateral toes are dorsiflexed. The 2nd, 3rd, and 4th metatarsal heads are depressed, and in time the soft tissues over the plantar aspect of these joints produce a convex surface which, with excessive use, becomes calloused and painful. High-heeled shoes aggravate the disorder.

to activate the small intrinsic muscles, the joints are mobilized by manipulation, and she is taught active exercises to plantar flex the proximal phalanges of the 2nd, 3rd, 4th, and 5th toes, together with rising on the toes with the foot inverted.

Osteochondritis of the Second Metatarsal Head

In certain cases, pain and discomfort are localized to the metatarsophalangeal joint of the 2nd toe. The syndrome begins in late

adolescence, and the patient may seek advice at any time thereafter. A callus may be present under this area.

Clinical examination usually reveals the Morton type foot with the long 2nd toe. The joint is tender on compression between the index and thumb, and plantar flexion of the digit produces pain.

Radiologic examination discloses changes in the metatarsal head, varying with the stage of the disease. The articular cartilage is first involved and the process goes on to a flattening of the head and gradual destruction of the

Syndrome of T. G. Morton's Toe (Plate 103)

In certain cases the metatarsalgia involves chiefly the lateral part of the forefoot. The pain is of a spasmodic type, burning in character and radiating up the adjacent sides of the 3rd and 4th toes. This pain is so severe that the patient often must remove the shoe on the street and massage the foot. A history of such incidents, with relief of pain by shoe removal, affords the clinical diagnosis. It is now known that the cause is a neuroma formed on the digital nerve just proximal to the head

Fig. 686 --Anteroposterior view of forefoot, right and left sides Morton's type foot with short *varus* first metatarsal. Note degenerative arthritis of right 2nd metatarsophalangeal joint (Freiberg's disease).

joint. There is usually a thickening of the metatarsal shaft, and many believe the etiologic explanation is a stress strain hypertrophy of this metatarsal bone with premature degeneration of the joint.

Treatment may be reserved to conservative measures, employing Morton's compensating insole with attention to well-fitted Oxford shoe with Cuban heel. When the symptoms warrant surgical intervention, resection of the metatarsal head with $\frac{1}{4}$ " of the neck gives satisfactory results.

of the metatarsal. The etiologic factor is probably friction and pressure between the metatarsal heads and ligaments. Degenerative changes are also noted in the digital vessels.

This disorder is cured by resection of the neuroma through a dorsal or plantar incision.

Summary

In diagnosing disorders of the forefoot the student must differentiate between splaying of the forefoot with metatarsalgia due to excessive use of the Morton type foot, osteochon-

dris of the 2nd and occasionally of the 3rd or 4th metatarsal head, *neuroma* of the digital nerve producing the syndrome of Morton's toe, callus formation and plantar warts under the ball of the foot, and finally march fractures of the 2nd, 3rd, or 4th metatarsal neck

Disorders of the Great Toe (Plate 104)

Hallux Valgus

This is the commonest disorder of orthopedic significance involving the hallux. The long axis of the great toe is deviated laterally and rotated internally in variable degrees, even

Anatomic Changes.—It is of fundamental importance in our understanding of the causation and especially of the treatment of hallux valgus to recognize that it is not an isolated derangement of the great toe but rather a part of a group of lesions involving the whole forefoot and finally the foot as a whole and the musculature of the leg.

Because of the forcing of the forefoot into the narrow wedge-shaped toe end of the shoe in walking, the great toe is deviated laterally and the remaining toes medially toward the long axis of the shoe. As the sole of the shoe is more rigid than the upper, this latter element stretches and the 1st and 5th metatarsals

Fig 687—Hallux valgus. Dorsal and plantar views of the forefoot, showing the deformity from the wearing of shoes. Note the flattening of the transverse arch and the crowding of the toes and the pressure callouses

to the point of lying transversely on the dorsal surface of the other toes with the nail facing dorsally

In some cases the etiologic factor is a congenital metatarsus primus varus, representing a throwback to the prehensile hallux. In most instances the deformity is acquired and is due to the mechanical factors resulting from improper shoes, such shoes are either too short, have too narrow a sole in the forefoot with a wedge-shaped toe-piece, or have too high heels. As these defects predominate in the female footwear, hallux valgus is 15-20 times more common in this sex

and toes are forced dorsally, while the 2nd, 3rd, and 4th metatarsals are displaced plantarward, giving the convex appearance to the ball of the forefoot with the usual designation, fallen or flattened metatarsal arch. Calluses under the 2nd and 3rd metatarsal heads follow in time. Further, the reverse of the hallux valgus deformity, namely, the *bunionette*, occurs in relation to the 5th toe.

As inadequate length of shoe exists, the toes must flex, and this flexion is accentuated by the muscular imbalance resulting from the high heels with shortening of the tendo achillis. Excessive dorsiflexion of the proximal

phalanx leads to clawing of the toes, and dislocation of the metatarsophalangeal joint of the 2nd toe is especially common.

Careful studies of the anatomic changes of the great toe have been made, and it has been found that the ligamentous change has been a gradual stretching of the ligament, binding the medial sesamoid to the 1st metatarsal head. As the great toe is displaced laterally, the sesamoids with the flexor digitorum longus remain fixed in relation to the 2nd metatarsal by the deep transverse ligaments. The dorsal and medial displacement of the 1st metatarsal opens up the first intermetatarsal space, and the sesamoids in relation to the metatarsophalangeal joint are seen to be abnormally lateral in position on the anteroposterior radiograph. The capsule is shortened on the lateral and lengthened on the medial aspect.

The lateral deviation of the 1st phalanx uncovers part of the articular cartilage of the metatarsal head. With irritation from the shoe, the angular prominence of the joint with the overlying bursa becomes inflamed, producing the characteristic *bunion*. There is no evidence that an actual proliferation of bone producing an exostosis occurs. The deformity, once initiated, is aggravated by the bowstring effect of the extensor hallucis longus and flexor hallucis longus. The corrective effect of the abductor hallucis is lost, with the plantar and lateral displacement caused by the rotation and deviation of its insertion on the proximal phalanx.

With the increasing structural changes the fitting of the shoe becomes more difficult, and there is a progressive insufficiency of the intrinsic musculature of the foot evidenced by generalized foot and leg pain.

Symptoms.—The female patient usually complains of pain in relation to the bunion and inability to carry on with her housework. Walking any distance is difficult. Suppuration may develop in relation to the bursa. Some are concerned about the cosmetic appearance, the difficulty of getting a properly fitted shoe, or the impossibility of wearing the style of shoe directed by fashion for social activities. In most cases the hallus valgus and bunion are part of a complex with as many facets for the orthopedic surgeon as facial rejuvenation presents for the plastic surgeon. It is often equally

difficult to satisfy the patients presenting these analogous problems.

Treatment.—The problem of correcting the metatarsus varus and hallus valgus in the adolescent is most difficult. Conservative measures include the reduction of overweight, exercises, the use of loosely fitting socks, and the fitting of shoes of adequate length and width with straight medial edges and low heels. With progressive changes, soft tissue operations have been employed. The most popular of these is that of McBride, in which the prominence of bone on the medial aspect of the joint is resected and the capsular ligaments shortened; through a second incision the lateral sesamoid is removed and the adductor tendon shortened and resutured to the neck of the 1st metatarsal. If the interspace is still excessive, strong chromic catgut sutures are used to encircle the 1st and 2nd metatarsals to hold them in closer approximation.

When the metatarsus varus predominates, attempts have been made to arrest the epiphyseal growth on the lateral side of the base of the 1st metatarsal. In the older patients, wedge resection and arthrodesis of the joint between the 1st cuneiform and metatarsal base have been advocated (Lapidus). Joplin has utilized a tendon transplant of the long extensor tendon of the 5th toe across the plantar surface of the metatarsals and through the 1st metatarsal neck. The tendon is fixed to the capsular tissues of the 5th and 1st toes after compressing the forefoot.

Following are the three most popular procedures for the adult female patient:

- 1 Simple resection of the prominence of bone on the medial side of the joint with the thickened bursa
- 2 The Keller procedure
- 3 The Mayo procedure

Before the patient is advised operative treatment, the surgeon should carefully evaluate the general and local factors. The patient's personality should be assessed, and an effort should be made to ascertain whether she will cooperate in postoperative exercises and in wearing sensible shoes. There is nothing more unsatisfactory than trying to satisfy the large, overweight female with outworn deformed feet who for years has been crucifying her

Plate 104.—Operations for Hallux Valgus.

appendages in the shoes of fashion. A telecast of the problems of the shoe salesmen with such patients would be a valuable propaganda weapon for better foot health.

The surgeon must also decide whether the cosmetic factor is predominant in the patient's mind or whether pain and suffering due to structural changes necessitate relief.

In the selection of the procedure to be followed, the circulatory status of the limb must be evaluated. Operative measures must be avoided in any case of arterial insufficiency, and, generally speaking, conservative measures should be used in patients over 60 years of age. When relief from pain is necessary, the older patient should be restricted to resection of the prominence of bone and thickened soft tissues.

For the cases in which more radical measures are indicated, and after a period of conservative therapy to mobilize and strengthen the feet, the Keller and Mayo operations are best.

The *Keller procedure* consists of the removal of the prominence of the metatarsal head together with the proximal one half to two thirds of the proximal phalanx. The soft tissues are sutured to assist in maintaining the corrected position.

In the *Mayo operation*, the head with a short length of the neck of the metatarsal is removed together with the prominence of the base of the 1st phalanx.

In both procedures it is sometimes of value to lengthen the extensor hallucis longus tendon. Where necessary, associated problems such as hammertoes and corns are treated at the same time. If both feet are involved, it is best to shorten the great toes an equal length to give a symmetric appearance.

The postoperative treatment consists of maintenance by strapping or plaster cast in the corrected position for 10-14 days. Following this, a careful program of strengthening exercises should be given for several months. At first moccasin slippers only are permitted. As the operative areas become less sensitive, shoes of proper width and with a Cuban height heel can be worn for increasing periods. A toe post may afford a certain support and comfort in the early period of weight-bearing in shoes.

Satisfactory results can be expected in properly selected cases when the operative procedure is combined with adequate preoperative and postoperative care.

Hallux Rigidus

This disorder is characterized by degenerative arthritis of the metatarsophalangeal joint. It occurs chiefly in the male sex and begins in adolescence. An extra long great toe, stubbing, and hyperextension injuries are predisposing factors.

The onset may be sudden, and the pathologic process appears to be an acute traumatic synovitis. If the joint is not protected the process is progressive, and loss of the dorsal area of the articular cartilage on the base of the phalanx ensues. A characteristic gait and wearing of the shoes have been noted. The gait develops to protect the sensitive joint, and the body weight is borne on the lateral aspect of the heel, the ball of the 5th toe, and directly to the proximal phalanx of the great toe instead of to the ball of the great toe. This produces a wearing of the outer side of the shoe heel, the outer side of the sole, and the area of the sole under the pulp of the great toe which is used for propulsion. There is an outward bulge of the upper on the outer side of the heel and forefoot, with convex deformity of the sole of the shoe from side to side.

Restriction of joint movements develops at first in dorsiflexion and finally in all directions. The joint in time takes up a position with some plantar flexion.

Clinical Picture.—The patient presents himself because of pain in one or both great toe joints. When only one is involved it is usually the one more utilized in propulsion.

In the acute phase the joint is swollen and tender and these features are most marked on the dorsal aspect. In time a thickened bursa may develop over this surface and is called a *dorsal bunion*. Movements, especially dorsal flexion, are painful and limited.

In the chronic stage there is a fixed plantar flexion of 10-15 degrees, and the range of plantar flexion is restricted. X-rays show little change in the early case, but the later changes include loss of joint space and osteophytic proliferation at the joint periphery.

Treatment.—The acute phase is best treated by rest to the joint. Ambulation on crutches is recommended. When the acute pain has subsided, a metatarsal type bar placed at the level of the metatarsophalangeal joints, instead of behind this line as for metatarsalgia, provides a rocker action protection. A shoe of adequate length and width must be worn.

The chronic painful stage can be treated by the Keller procedure or by arthrodesis of the joint. Both operations relieve the pain and permit satisfactory function.

Sesamoids

The two sesamoids under the great toe are important anatomic structures of the ball of the foot.

Congenital variations include *bipartite sesamoids* which must be differentiated from fracture. The history of a direct injury followed by local swelling, bruising, and tenderness will assist the clinician. X-rays should be taken of both feet. Congenital lesions are usually bilateral, and the line of division is usually smooth when compared with the irregular fissuring found in fractures.

Irritation of the sesamoids can occur from contusion or intermittent pressure in feet with a poor soft tissue covering. The best treatment of *sesamoiditis* is by pads arranged to diminish the pressure on the sensitive bones. Excision is rarely necessary.

Gout

The great toe is the site of election for this metabolic derangement, and patients are seen presenting the clinical picture of the acute, subacute, and chronic stages. Gout is included here because of its frequency and also to remind the physician to consider it as an etiologic factor in painful disorders of the great toe joint.

A history of recurrent attacks of pain related to this area with complete freedom from discomfort in the intervening periods is characteristic of the early stages.

Excruciating pain, reddening of the medial and dorsal aspects of the joint spreading over the dorsum of the foot, and extreme discomfort on walking are additional signs.

In the chronic stages, radiographic evidence is available in the bitten-out appearance of the head of the 1st metatarsal. Tophi in ears and involvement of other joints may be noted. (See Fig. 565.)

Treatment.—The acute attack is best treated by rest from work and weight-bearing. The foot is elevated and cooling lotions applied. *Heat aggravates whereas cold relieves the pain.* A light diet with the addition of vitamin capsules is prescribed, and fluids are restricted. Colchicine is specific and 0.5 mg. is given hourly (usually 8-10 doses) until diarrhea occurs. *Mistura comphorae composita* (opioric) is given to diminish the intestinal discomfort. Intravenous injection of 3 mg. colchicine is dramatic. Butazolidin 800-1000 mg. daily is also valuable.

The chronic case must be advised a diet low in fat and red meat. Alcoholic beverages are prohibited. Salicylates and a maintenance dose of colchicine are beneficial. Moderation in drinking, exercise, and sexual activities will be found the best way of life.

Disorders of the Toes Other Than the Hallux

Clawing of the toes is the most common disorder. It should be remembered that muscular balance of the toes is the same as for the fingers, and that clawing of the toes is a result of imbalance of the short intrinsic musculature.

The extensor digitorum longus supplements the action of the extensor digitorum brevis acting chiefly on the proximal phalanges of the toes, producing dorsiflexion. The flexor digitorum longus and flexor digitorum brevis act on the distal phalanges, producing flexion. The interossei and lumbricals insert into the dorsal expansion and produce flexion of the proximal phalanges and extension of the distal phalanges as in the fingers.

The usual claw deformity of these toes consists of hyperextension or dorsiflexion of the proximal phalanx and flexion of the distal phalanges. This position is produced by overactivity of the long and short extensors, reciprocal inhibition of the flexors, and weakness of the interossei and lumbricals. The high heel element of the female shoe is

obvious cause of such a deformity. Calluses develop on the prominences of the interphalangeal joints from the intermittent pressure of the shoe.

Hammer toe and Mallet Toe
(Plate 103)

When the clawing is confined to one toe, the designations above are used. This most frequently involves the 2nd toe. *Hammer toe*

consists of marked dorsiflexion of the proximal phalanx with plantar flexion of the 2nd phalanx. The distal phalanx may be hyperextended, neutral, or hyperflexed. The condition may be familial and unilateral or bilateral. When the deformity consists only of a marked plantar flexion of the distal phalanx, the name *mallet toe* is given.

Such deformities may be symptomless, or the patient may seek assistance because of pain

Fig 658—Bilateral hammer toes involving the 2nd toe. Note also the pressure points over the interphalangeal joints.

from callus or corn formation, pressure on the nail, or for cosmetic reasons.

In children, strapping may be of some help, but supervision for many months by the parents is essential to produce lasting results.

When treatment is desirable in the adult, arthrodesis of the proximal phalangeal joint after correction of the deformities by tenotomy and capsulotomy gives excellent results. The straight position of the toe is maintained for 4 weeks by a fine Kirschner wire, which is then removed under local anesthetic as an office procedure.

Bunionette

The *bunionette* for the 5th metatarsophalangeal joint is the counterpart of the *bunion* for the great toe. It consists of a bursal enlargement over the angular projection at this joint.

Conservative measures of treatment comprise correction of faulty shoes and relief from pressure by application of protective pads.

When the deformity is cosmetically unsightly and pain is severe, removal of the prominence of the head of the metatarsal and phalangeal base may be considered.

Overlapping Fifth Toe

(Plate 105)

This is a congenital lesion involving the 5th toe which shows a tendency for adduction of the digit at the metatarsophalangeal joint. This may develop into a transverse dorsal displacement of the toe, interfering with the proper fit of the shoe.

Correction in the very young can be obtained by the Budin sling. However, this often fails, and operative correction by extensor tenotomy, capsulotomy, and plication of the lateral capsule can be used. Some adult patients prefer excision of the proximal phalanx or amputation of the digit, especially when associated with a persistent soft corn.

Disorders of the Nails

The toenails present a considerable number of problems to the practitioner and advice is frequently sought because of their improper

care. The soft, irregularly shaped nails of the aged disclose the nutritional changes occurring in arterial insufficiency. Gangrene of the limb can develop from misdirected attempts to pare such nails or from neglect of associated infection.

Ingrowing Toenails

(Plate 106)

This common disorder most frequently involves the nail of the great toe. Tight shoes, shrunken socks, and improper paring of the corners are the common etiologic factors. In some patients malformations of the nail resulting from trauma or of a congenital origin constitute the predisposing cause.

Plate 106 shows the proper way in which the nail should be pared. The corner on each side should project beyond the flesh. If the corner is cut off, the flesh is gradually pushed in by the pressure of the other toes, the socks, or the shoe. With growth, the nail is too wide for the space, and ulceration or cutting of the flesh by the sharp corner occurs. Pain from this pressure of flesh against the sharp nail edge develops, and it is only a matter of time before infection ensues. Thus it can be seen that the designation *ingrowing toenail* is a misnomer. We are really dealing with ingrowth of the flesh. A vicious cycle is established, and the patient again cuts the corner of the nail to relieve the pain.

Usually by the time the patient consults the physician infection is present and a granulomatous mass projects in relation to the nail edge. Treatment at this stage consists of rest from shoes, socks, and weight-bearing, hot soaks, and the administration of antibiotics in cases of spreading infection. When the inflammation has subsided, a wedge of absorbent cotton is inserted under the corner of the nail to relieve the direct cutting of the flesh. It is sometimes possible with a well-intentioned patient to clear the trouble and arrange for adequate care of the nails in the future.

Frequently the condition is so severe that removal of the nail under general anesthesia is necessary. The infiltration of the infected great toe with local anesthetic should be avoided, as it may lead to spread of the infection and even to gangrene in the older patient. When the

CLINICAL SYMPOSIA 9 81, 1957.

infection has been cleared, advice as to the proper care of the nails must be given, and supervision is required in many cases to see that it is properly followed.

In neglected and recurrent cases, especially when malformation of the nail is a predisposing factor, removal of part of the nail with its nail bed is indicated. Sometimes it is better to remove the whole nail with its bed together with part of the phalanx, and this results in a permanent cure. All remnants of the proximal corners of the nail bed must be secured to prevent regrowth leading to a horny projection through the scar.

In the early ambulatory phase of these various painful conditions a metatarsal bar on the shoe should be worn.

Oncychogryphosis

This is an overgrowth of the nail, so called because of its resemblance to a ram's horn. Different etiologic factors such as irritation of the nail bed by direct trauma, intermittent pressure, and infection may be cited as possible causes.

Treatment.—The size may be controlled by regular attention with an electric burr. Attempts to cut with standard clippers are usually painful to the patient and often unsuccessful. Radical measures include the operation of complete removal of the nail and nail bed as performed for the ingrowing toenail.

Subungual Exostosis

The distal phalanx of the great toe is the occasional site for the development of an exostosis. The bony proliferation projects from the dorsal surface under the nail, causing pain and deformity.

Treatment.—The exostosis is best exposed through a fish-mouth incision, with complete removal of the bony growth including its base.

Common Dermatologic Disorders

Hyperidrosis, or excessive sweating, may involve the feet. It occurs in the overweight individual with chronic foot strain, especially in the summer months. In other individuals it appears to be a vasomotor disorder. At times the

action of bacteria on the moist detritus gives an offensive odor to which the name *bromidrosis* is given. The feet are wet and clammy, and there are often an associated fungous infection and plantar warts.

Treatment should be directed to correct any mechanical dysfunction. The patient should be advised to wash the feet carefully morning and evening in hot soapy water. The parts must be thoroughly dried and any detritus removed. The skin should then be swabbed with rubbing alcohol.

(titanium
white co-
should be

newed until diminution of the sweating occurs; those with nylon mesh uppers give good aeration. In resistant cases dehydrating solutions such as Burow's (1/20 aluminum acetate) or formaldehyde 6 drams to a quart of water can be used for foot baths. Pro-Banthine has been helpful in certain cases. X-ray therapy is dangerous and should be avoided unless used by experts.

Epidermophytosis, or athlete's foot, is a fungus infection and is frequently associated with hyperidrosis. It is almost universal in persons frequenting the public swimming pools and athletic clubs. The characteristic sodden and cracked white skin between the toes is well known, but the more extensive skin involvement on the soles, the contact spread to the anal and eyelid areas, and the id reaction on the hands are often overlooked. Secondary infection by streptococci and staphylococci may be a serious complication.

Treatment.—Proper foot care with careful washing, drying, and powdering, together with the use of clean socks and shoes, is essential at all times. In public places the use of disposable slippers and antiseptic foot baths should be utilized.

Many agents have been used for eliminating the fungus. When uncomplicated by infection, the unsaturated fatty acids such as propionic and undecylenic acids (Desonex) have been useful. Drying powders such as titanium tannate (Metanium) can be used by day. Exposure to salt water and sunshine is most efficacious.

When infected, antifungicidal remedies should not be used. The infection, when severe

of a narrow shoe. Pressure of the medial surface against a prominent base of the proximal phalanx of the 4th toe or from the deformity of an overlapping 5th toe is the usual cause of the soft corn in the 4th interspace.

Treatment of the Hard Corn.—Protection from intermittent pressure by properly adjusted footwear and a protective pad are the primary measures. Careful paring and enucleation of the corn by a chiropodist will give relief. The application of a corn plaster can be used to soften the corn before removal.

Treatment of the Soft Corn.—The mechanical derangement producing the pressure must be removed. When this consists of overlapping toes, prominence of the base of the 4th or 5th phalanx, or incorrect shoes, such must first be corrected. The excess detritus is removed and the toes kept apart and ventilated with lamb's wool. Sweating can be diminished by dusting with titanium tannate (Metanium) powder. Cauterization of the corn may be performed, using electrocoagulation or 50-60% silver nitrate solution. Removal may be secured by one or more applications. Care must be taken to prevent too severe a reaction from treatment, which may result in a deep ulcer with superimposed infection.

Radical Treatment for Hard and Soft Corns.—When the 5th toe is seriously involved with both hard and soft corns, resection of the proximal phalanx (fillet operation) is the most successful procedure and is preferable to amputation.

Treatment of Calluses.—Calluses can be kept in check by regular paring, but cure can only be achieved by the use of mechanical supports or orthopedic correction of deformities. Salicylic acid (40-80%) plasters can be used to soften the callus before paring. A moleskin adhesive covering of the callus is a worth-while palliative protection.

Chapter 41

Infections of Bone

H Fred Moseley, D.M.

Osteomyelitis is the term used to designate the inflammatory process in bone. When the process is confined to the epiphysis, it is called epiphysitis, and when the inflammation is localized to the surface of the bone beneath the periosteum, it is named periostitis. The inflammatory process may vary in extent and severity and is classified as acute or chronic in nature.

Bacteria may metastasize to bone in the course of a bacteremia or septicemia associated with a systemic infection, resulting in the disease *acute hematogenous osteomyelitis*. In other cases organisms may be directly introduced as a result of trauma which causes open or compound fractures. If the contamination is not adequately removed by surgical débridement, infection of the bone results, and this type is called *primary osteomyelitis*. When bacterial infection extends from a neighboring soft tissue inflammatory process such as an abscess or ulcer to involve bone, the type of lesion is termed *secondary osteomyelitis*. The characteristic reaction of bone to the inflammatory process is determined by the rigid nature of osseous tissue and by the arrangement of the blood supply.

The Structure of a Long Bone.—Osseous tissue consists of an organic matrix upon which calcium salts are precipitated to give it a rigid character. A typical long bone comprises a compact bony cylinder called the *diaphysis* which contains the *medullary cavity*. At each end there is an *epiphysis* of cancellous bone covered by articular cartilage which enters into

the formation of the neighboring articulation. Between the epiphysis and diaphysis in the maturing individual lies the area of maximum growth called the *epiphyseal plate*. The diaphyseal side of this epiphyseal plate receives the richest blood supply. In this area the nutrient vessels end in large capillary loops, and bacteria carried by the blood stream tend to stagnate there. Besides, in the young patient, twisting strains find in this area the weakest point in the bone-joint structure. It is well known from epiphyseal fracture separations, injuries, and infections is named the *metaphysis*.

The Blood Supply of a Long Bone.—The work of Lexer remains the classic study in this field and the arrangement can be understood by reference to the blood supply of the tibia. The main nutrient artery enters on the posterior surface of the upper third of the tibia and divides into an ascending and a descending branch which proceed to the respective epiphyseal plates. The branches of the artery pass longitudinally in the medullary canal and in the compact bone through the longitudinal or *Haversian canals* which contain, in addition, the nerves and lymphatics. Besides the arterial circulation to the diaphysis, a second supply derived from the periosteal circulation enters the compact bone along the *Volkman's canals* which run tangentially to the surface. At each end of the bone, arteries enter the epiphysis and the metaphysis separately from the rich

arterial anastomosis around the joint. Because of the arrangement of the vessels in rigid canals, any inflammatory process in bone tends to raise the tension around the vessels and soon causes occlusion and thrombosis. The inflammatory processes within the bone soon release their tension by spread along Volkmann's canals to the subperiosteal area. This extension by stripping off the periosteum interrupts the periosteal circulation and again leads to interference with the nutrition of bone, producing local death of tissues.

a *sequestrum*. While this process of separation and extrusion is taking place, the periosteum, which has been raised from the bone by the inflammatory process, proliferates to give strength to the bone as a whole and produces a cylinder of new bone around the damaged area. This new cylinder of repair bone is called the *involucrum*. The area of sequestration sooner or later communicates with the exterior by *cloacae* traversing this involucrum, and it is through these sinuses that nature attempts to extrude the sequestrum.

Fig 690—The circulation in a long bone

The Reaction of Bone to Infection.—The main effect of the inflammatory process on bone is the interference with its nutrition by occlusion and thrombosis of the blood supply. Bacterial toxins also play their part in destroying the living bone cells or osteoblasts. This local destruction of bone is called *necrosis*. If an area of bone has undergone necrosis, the adjacent living tissue reacts to separate and extrude the dead portion. When the area of necrosed bone has been separated, it is called

in flat bones such as the skull and pelvis, the reaction to the infection differs from that in long bones and corresponds more to the cellular death of tissue seen in soft tissue ulceration. This process in bone is called *caries*. Most studies of the progress of infection in bone are made by repeated radiologic examinations. During the early inflammatory process, decalcification due to the intense hyperemia causes a loss in the normal density of the x-ray shadow. This change in bone density and radiologic

appearance is referred to as *osteoporosis*. The increased density that follows ischemia of bone and repair with scarring is termed *osteosclerosis*.

ACUTE HEMATOGENOUS OSTEOMYELITIS

Before the advent of penicillin and the other antibiotic agents, few infective processes afforded the surgeon greater difficulty in treatment than acute hematogenous osteomyelitis. In the fulminating type, death from the septicemia and generalized pyemic abscesses throughout the body was of frequent occurrence. In cases of lesser systemic severity, the extensive necrosis of bone with subsequent sequestration, sinuses, recurrent abscesses, and adjacent joint ankylosis often left the patient a cripple for life. Today, with early diagnosis and appropriate antibiotic therapy, the systemic and local processes can be rapidly controlled, and a dramatic improvement in the mortality and morbidity rates has resulted.

Bacteriology.—The vast majority of cases of acute osteomyelitis (90%) is caused by *Staphylococcus pyogenes*. A relatively small number is due to *Streptococcus pyogenes* or *Diplococcus pneumoniae*, and rare individual cases may be caused by other microbes. In acute hematogenous osteomyelitis the causative organism can be isolated from the blood stream or the local lesion in pure cultures. In primary or secondary osteomyelitis mixed infections may be found and have to be treated accordingly. *Streptococcus pyogenes* and *D. pneumoniae* infections are more prone to involve the epiphysis and the neighboring joint.

Pathogenesis.—The most common source of staphylococcal osteomyelitis is an infection of the skin, furuncle, or carbuncle, etc. From the cutaneous lesion, invasion of the blood stream occurs, with or without clinical manifestations, and the organisms are carried to the metaphysis of the bone. The most common site involved is the region of the knee, including the upper end of the tibia and lower end of the femur. The ankle is second in frequency, and the metastasis involves the lower end of the tibia or the lower end of the fibula. The upper end of the humerus and upper end of the femur are also common sites, but it must

be remembered that any metaphyseal area may be involved. Re-entry of bacteria from the osseous lesion into the circulation may in turn cause septicemia or further metastatic foci in other bones or organs.

Various factors predispose to the development of this disease. Among these the age of the patient is most important. The age period marking the maximum incidence is 8-12

Fig. 691.—Museum specimen of chronic osteomyelitis of the tibia showing involucrum, sequestrum, and cloacae.

years, but all ages from the first week of life until epiphyseal closure around 20 years may be affected. Boys are more commonly afflicted than girls, and this sex incidence lends support to the theory that juxtaepiphyseal strain caused by an injury is a predisposing factor. As previously mentioned the area of the metaphysis is the weak link in the bone joint structure in the growing patient, and strains may produce a hematoma affording a nidus for circulating bacteria. Lowered resistance and climatic influences are often mentioned as contributing factors. Cases of osteomyelitis are more common in the late winter months in the north temperate climates and in the poorer classes of the population.

Fig 692—The spread of osteomyelitis in a long bone

The Pathologic Spread in Bone.—The accepted ideas on the spread of the infection from the fixation point in the metaphysis follow the observations of Starr and are summarized in Fig. 692. As the tension rises from the suppurative process, the inflammation extends into the cancellous tissue and down the medullary canal. The next extension is outward to the subperiosteal space along the Volkmann canals. The epiphyseal plate affords a strong

barrier to the passage of bacteria into the epiphysis and thus into the joint. Once the subperiosteal space is involved, the tension again rises and the periosteum is stripped off the bone and the shaft infected via Volkmann's canals. Because of the close relation of the subperiosteal abscess to the synovial reflexion and joint capsule, an effusion into the joint may occur, and in time a pyogenic arthritis develops in the neglected cases.

In certain cases the embolism may affect the metaphyseal area only; in other cases the embolus may block either the main ascending or the main descending branch of the nutrient artery, or the entire vessel may be blocked in the initial stage. These different sites of embolism determine the pattern of the inflammatory process and have been emphasized by Wilensky.

As the bone is rendered ischemic by the thrombophlebitis and also by the cellular death caused by bacterial toxins, the process of sequestration begins. In the neglected cases in the preantibiotic era the separation was completed in the average case in 6-8 weeks.

Clinical Types of Acute Hematogenous Osteomyelitis.—There are three main clinical types of this disease determined by the severity of the systemic and local process:

1. The fulminating type in which septicemia and pyemia predominate and the bone lesion is of secondary importance.
2. The type where the blood stream invasion and osteomyelitic process are practically silent. The bacteremia passes unnoticed and the osteomyelitis becomes clinically apparent with the development of a subacute or chronic Brodie's abscess.
3. The common type in which a septicemia of varying severity exists for several days and the osteomyelitic process predominates.

Clinical Picture.—The clinical picture will vary, depending on the intensity of the septicemic and osteomyelitic processes.

In the fulminating type the young patient is desperately ill and frequently delirious and irrational. The temperature ranges above 104° F., the pulse is 120-160, and the leukocyte count 25,000 or more. The patient is often dehydrated. Complaints may be of fleeting pains

from one bone or joint to another. The general symptoms and signs far overshadow any local signs in bone which may not be discovered. A blood culture is usually positive if taken just before the peak of the temperature, and the prognosis can often be judged by the number of colonies cultured and the number of days the septicemia persists. Before the advent of penicillin the majority of these patients died from generalized pyemic abscesses in brain, lung, kidney, and other organs.

The symptoms and signs will be both general and local.

The general features will be determined by the intensity and duration of the septicemia. The patient will be ill with a raised septic type of temperature, rapid pulse rate, and leukocytosis. Repeated blood cultures in the early stages will be positive and enable the isolation of the organism and study of the antibiotic sensitivity. As previously stated 90% or more are due to the staphylococcus.

Fig. 693 --X-rays showing early changes of acute hematogenous osteomyelitis

A, Primary lesion shown 10 days after the onset of disease

B, Several weeks after evacuation of subperiosteal abscess with primary closure and antibiotic therapy. Note decalcification and periosteal thickening

In the *silent type* with the development of a Brodie's abscess, the general symptoms and signs are negligible. The patient complains of an increasing pain or aching at the extremity of a long bone with some limitation of function of the neighboring joint. In the lower limb a limp or a tender enlargement of the bone may be noted.

In the *common type* of case with a septicemia of several days' duration and an acute inflammatory process in one of the long bones,

The local symptoms are those of a circumscribed acute infection. The patient complains of an increasing intense and throbbing pain situated deep in the limb which will be localized by the examiner on palpating the area of maximum tenderness. The area may be swollen and reddened. If the process is of several days' duration, a subperiosteal abscess with fluctuation may be present.

Radiologic examination in the early stages is generally negative, but an area of rarefaction

near the epiphyseal line will be apparent after 7 or more days.

Differential Diagnosis.—The history of a sudden illness with acute pain in one of the limbs in a young active child or adolescent should suggest an acute hematogenous osteomyelitis. The diagnosis will be assisted if there has been a recent skin or upper respiratory infection. In the infant an infected umbilicus should be looked for. Acute osteomyelitis must be differentiated from acute rheumatism. In *acute rheumatism* the pain, tenderness, and swelling around a joint usually appear at once, whereas in acute osteomyelitis the pain generally precedes the swelling of the joint by 2-3 days. Besides, in acute rheumatism it is customary to have the pains in several joints and often fleeting from one to another. Acute osteomyelitis is characterized by exquisite tenderness of the bone, and the young patient recoils from the examiner. It is best to regard any acute process at the end of a long bone in the child or adolescent as acute hematogenous osteomyelitis and treat promptly as such by appropriate antibiotic therapy. If the process is rheumatic in character, the response to antibiotics will not be satisfactory but will usually be dramatic when salicylates are administered.

In *poliomyelitis* the young patient may complain and give signs of pain and loss of function in one limb, but characteristically the patient is not so ill nor the local signs so marked as in acute osteomyelitis. Neck rigidity will be present, and lumbar puncture will reveal increased cells in the cerebrospinal fluid.

The differentiation from a *sprain* or *fracture* may be required, but in these cases the systemic signs of an infection are lacking. However, the association of juxtaepiphyseal injuries with osteomyelitis must be remembered. Radiologic examination often discloses minor degrees of epiphyseal injuries with flakes of bone torn off with the periosteum or fragments of the metaphysis fractured.

Treatment.—The treatment of acute hematogenous osteomyelitis had undergone great changes by the time the chemotherapeutic and antibiotic drugs had arrived. More and more, surgeons were devoting their attention to supportive general treatment directed toward

the septicemia and treating the local process in bone with rest to the part and masterly inactivity from an operative point of view. The results of radical removal of cortical bone and exposure of the medullary canal had not been satisfactory and many surgeons were content to open the periosteum and place fine drill holes into the metaphyseal area to lessen the tension and afford drainage. The use of the antibiotic drugs has made the treatment of acute osteomyelitis practically a medical problem.

The principles underlying the modern treatment may be summarized as follows:

1. The patient should be treated in bed and general supportive measures given. Small transfusions are valuable in the early and late stages.

2. Blood cultures should be taken to isolate the specific organism and to study its antibiotic sensitivity.

3. While awaiting the results of blood culture, penicillin in massive doses and streptomycin should be given. In the fulminating type, intravenous penicillin should be administered. If the organism does not respond promptly to this regimen, the most suitable antibiotic determined by the sensitivity should be tried in place of penicillin.

4. The bone involved should be placed at rest in a plaster-of-Paris splint with immobilization of the adjacent joints. Should the patient be seen late and a subperiosteal abscess be present, bacteriologic study of the aspirated pus should be made. The subperiosteal area may be irrigated and local penicillin, 300,000 units, instilled. Similarly, if an effusion into the joint is present, it should be aspirated and the fluid cultured. If bacteria are present, penicillin should be instilled.

It may be mentioned that there are those today who believe that the local treatment should include the incision of the periosteum and washing out of the subperiosteal abscess and primary closure of the wound. Others prefer to add to this multiple drill holes into the metaphyseal area to diminish the tension. More and more, the cases are being diagnosed and treated at an earlier stage. It can almost be stated that if prompt treatment by the appropriate antibiotic is given within 5 days of the

onset, the general and local processes can be controlled. Indeed, according to Trueta, if penicillin treatment at the level of one million units a day is started within 48 hours of the onset of the disease, it appears to prevent altogether the bone changes usually detectable by roentgenographic examination. After this period there is a greater incidence of bone necrosis leading to sequestration.

CHRONIC OSTEOMYELITIS

Patients presenting chronic osteomyelitis include the end results of three groups of cases in which the acute primary infection has not been eradicated and the bacteria have become organized in the scarred and devascularized bone. The radiologic examination shows osteosclerosis and probably sequestration.

Fig. 694—X-ray showing late changes of chronic osteomyelitis

Complications.—In the fulminating cases, toxemia and pyemia with multiple metastatic abscesses in the organs and serous cavities lead to death.

In the cases which are neglected, sequestration with the development of recurrent abscesses and sinuses are the clinical features of one type of chronic osteomyelitis. Such cases so frequent in the pre-antibiotic era should soon become uncommon.

The three groups of cases:

1. Late cases of acute hematogenous osteomyelitis

2. *Open fractures*, including those due to war wounds with presence of foreign bodies such as shell fragments; *closed fractures*, infected at operation by penicillin resistant staphylococci, as a result of the increasing use of open reduction and internal fixation for such cases

Fig 695—Tuberculous abscess of upper tibia with involvement of the knee joint, treated by resection of the diseased tissues, packing of the cavity with cancellous bone chips, and compression arthrodesis of the knee

A and B, Preoperative appearances, anterior and lateral views
C and D, Postoperative appearances 3 months later

3. Chronically infected bone from spread from adjacent soft tissue infections

The cases of chronic osteomyelitis following each of these primary types of infection are becoming less frequently seen because of the prompt and efficient antibiotic therapy in the early stages, but during World War II countless numbers of Group 2 were seen and great advances made in their treatment. The time has come when the severe general reaction to such chronic infections with weight loss, secondary anemia, lowered plasma proteins, and amyloid disease is rarely seen.

The principles underlying the local treatment of the infected bone are based on the fact that the bacteria are protected from antibiotic drugs by the scarred and devascularized bone. It is therefore necessary to remove such bone, scarred and adherent skin and soft tissue, together with any sequestra and foreign bodies that may be present. This is done after the general health has been improved by appropriate transfusions and nutritional and vitamin therapy as is required, and under the protection of antibiotics begun 3-5 days preoperatively. A careful bacteriologic study of the wounds is made prior to operation, and the nature of the mixed infection is determined. Where possible the local condition is improved by topical application of antibiotics prior to operation.

Once the dead bone and scarred tissues have been removed, the wound is closed with a petrolatum pack for 7-10 days. In some cases the surgical procedure results in the saucerization of a long bone, in others an exteriorization of a cavity. At the end of this period if a clean granulating surface is provided, the area is covered with a split-thickness skin graft. In certain cases where a satisfactory vascular bed is present, primary skin grafting is possible. Small sequestra may separate through such a covering, but when the skin graft has finally closed the area, consideration may be given to filling defects by various procedures, which include the use of cancellous bone chips to fill cavities and the transfer of muscle, fat, and skin flaps to improve the cosmetic appearance.

By such means and with the protection of systemic and local antibiotic therapy, many

limbs previously amputated and others presenting recurrent abscess and sinus formation can now be cleared of their chronic osteomyelitis.

SPECIFIC TYPES OF OSTEOMYELITIS

Typhoid osteomyelitis is now a rare condition due to the public health measures controlling the water and milk supplies. It is mentioned to remind the student that in typhoid cases involvement of bones such as the tibia, rib, sternum, and vertebrae may occur in the 2nd or 3rd week of the disease or even years after the disease has subsided. In these cases the abscesses, if incised, will discharge pure cultures of typhoid bacilli and can cause contamination of other patients.

Tuberculous osteomyelitis is also today of decreasing significance. Usually the initial lesion is in the juxta-articular area and involves the corresponding joint. This has been discussed in the general section on joints and in the section Pott's disease in Disorders of the Vertebral Column.

Occasionally, tuberculous infection is a cause of a chronic abscess in bone and is a differential diagnosis in cases of Brodie's abscess. Rarely, one sees an expansile swelling in the small bones of the fingers due to this cause, which is called *tuberculous dactylitis*.

Syphilitic infection of bone is also a relatively rare condition from the surgical standpoint. Efficient and early treatment of the initial lesion in the free clinics has caused the disappearance of such cases.

Chapter 42

Tumors of Bones and Joints

J. Gordon Petrie, M.D.

Tumors of the bone may be benign or malignant. In addition metastatic tumors of bones arise from malignant growths in other parts of the body.

GENERAL CONSIDERATIONS

The *benign bone tumors* grow slowly, do not metastasize, and rarely show abnormal blood findings.

The *primary malignant bone tumors* vary in rate of growth, do metastasize, and frequently show blood changes to help in differentiation.

The *metastatic tumors* to bone are most frequently from carcinoma of the breast, prostate, kidney, thyroid, and lung.

The exact cause of bone tumors is unknown. Trauma is usually considered an important factor in the development of certain bone tumors.

The patient suspected of a bone tumor should have a careful history, a complete general examination, a hemogram, urinalysis, blood serologic and chemical determinations, a roentgenogram and a biopsy.

Laboratory Examination.—Certain types of bone tumors produce changes in the blood and

TABLE 37

6. Fatty tissue series	Lipoma	Liposarcoma

urine which may help in their differentiation. *Alkaline phosphatase* is secreted by proliferating cartilage cells and osteoblasts and excreted by the liver, so there is an increase of alkaline phosphatase in the blood with liver impairment, and also during the active phase of bone growth. This is found also in the healing of fractures and in certain bone tumors such as osteogenic sarcoma and in patients with bone metastases especially from the prostate.

Acid phosphatase is an enzyme found in large amounts in hypertrophy or in carcinoma of the prostate gland. When the carcinomatous tumor has ruptured the capsule of the gland

amputation is carried out on a patient with any bone tumor. The wound after surgical biopsy must always be closed and never packed or drained.

BENIGN TUMORS

Osteoma

Osteomas or exostoses frequently arise from a bony surface. Those arising from the center of the bone are known as enostoses. An osteoma may be compact or cancellous. The former frequently originate from the periosteum of membranous bones, e.g., skull or face.

Fig 696—Lipoma of bone. A very rare benign tumor of bone that responded completely to curettage and packing with bone chips.

and metastasized to the soft parts or to the bones, there is, in about 70% of cases, an increase of acid phosphatase in the circulating blood.

The *Bence Jones protein* may be found in the urine in 60% of cases of multiple myeloma. Bone marrow biopsy from the sternum is positive in 95% of cases of multiple myeloma.

In all bone tumors where there is any doubt as to diagnosis, a biopsy should be done. A biopsy must always be performed before an

Treatment by excision is indicated when such a tumor causes pressure on nerves or deformity. A large group of exostoses originate at the ends of long bones and are often multiple, hereditary, and associated with other abnormalities.

Osteoid Osteoma

This tumor, described by Jaffe in 1935, occurs most frequently in patients 10-25 years of age. In general, long bones are affected. There is slight swelling and localized tender-

TABLE 38

CHARACTERISTICS OF PRIMARY BONE TUMORS

TYPE	INCIDENCE OF ALL BONE TUMORS	AGE (YR.)	SEX	TYPES OF BONES AFFECTED	ORDER OF FREQUENCY	SITES OF ORIGIN IN BONE	METASTASES	X-RAY APPEARANCES	HISTOLOGY

ness but no heat or redness. The roentgenogram shows a zone of sclerosis, in which is an area of rarefaction and a nidus. Either sex may have the tumor. The differential diagnosis includes Brodie's abscess, Garré's sclerosing osteomyelitis, eosinophilic granuloma, Paget's disease, and fibrous dysplasia. The differentiation may be made by the history, the x-ray, and at times the biopsy. The treatment is surgical excision of the nidus; if removal is incomplete, the tumor continues to grow and

to cause symptoms. Histologically, one sees cellular proliferation (osteoblasts), patches of osteoid tissue, and areas of calcified atypical bone.

Osteochondroma or Cartilaginous Exostosis

This common tumor occurs chiefly between 10-30 years of age and is most frequently found in the region of the knee joint. The symptoms are usually associated with interference of function of the joint or tendons.

Surgical excision should be carried out. These tumors are often encapsulated and can be readily shelled out. Degenerative changes occur so that myxomatous degeneration, cyst formation, calcification, and ossification are frequently seen. Geschickter and Copeland state that malignant transformation occurs in 7% of cases. The growth then becomes much softer, the regularity of cell arrangement is lost, and invasion occurs.

Chondroma

This tumor occurs centrally (enchondroma) in the small bones of the hands or feet or projects from the surface of the bone (exenchondroma). The centrally occurring chondromas cause expansion of the bone and are best treated by curettage and by filling the defect with bone chips.

Fig 698—Chondroma (enchondroma) of phalanx

Giant Cell Tumor (Osteoclastoma)

This tumor occurs between 15-30 years of age. The lesion is locally destructive and tends to recur but does not metastasize. The commoner locations are the lower end of the femur, the upper end of the tibia, and the lower end of the radius. They may also occur in the jaw, pelvis, tendon sheaths, bursae, and capsules of joints. The tumor arises in the epiphyseal area of the bone as a soft, dark red, hemorrhagic mass, which is frequently lobulated and causes expansion. Periosteal new bone does not occur unless a pathologic fracture has been present.

Appearance of the Tumor.—The tumor is cystic, hemorrhagic, and traversed by bony trabeculae. The cortex is extremely thin. On microscopic section it shows three types of cells:

1. Small round cells which are numerous
2. Large multinucleated (15-20 nuclei) giant cells
3. Spindle cells

The stroma shows spindle cells and also vascular spaces.

The treatment of choice is curettage and insertion of bone chips unless the tumor occurs in a bone where resection is possible. Curettage must be complete, as recurrences follow those incompletely treated. If a recurrence follows, then a thorough curettage should again be done and the cavity filled with bone chips, or, if possible, excision of the tumor and replacement of the defect with bone grafts and bone chips.

Röntgen therapy should be used only on inaccessible tumors or when excision would lead to mutilation or functional impairment.

Some persons doubt that there is such a tumor as a malignant giant cell tumor.

In the differential diagnosis of giant cell tumor of bone the following should be considered: nonosteogenic fibroma, osteogenic sarcoma, simple (unicameral) bone cyst, aneurysmal bone cyst, benign chondroblastoma, fibrous dysplasia, and the bone lesions of hyperparathyroidism.

Nonosteogenic fibromas are often discovered incidentally on x-rays of older children. Microscopically the predominant cells are fibroblasts.

Fig 699—Giant cell tumor of lower end of tibia, before and after operative excision, and filling of cavity with cancellous bone chips

The *simple (unicameral) cyst* has a wall of fibrous tissue which may contain numerous benign giant cells. The cystic spaces contain gas or fluid unless a fracture is present, when they may contain blood.

The *aneurysmal bone cyst* has spaces filled with unclotted blood and portions of solid tissue containing many giant cells.

The *benign chondroblastoma* shows chondroid ground substance which may show degeneration and later calcification.

Fibrous dysplasia may show giant cells but will also present irregular bony trabeculae or areas of osteoid tissue.

Hyperparathyroidism shows fibrous replacement of bone in which many giant cells can be found. There are a consistently elevated serum calcium, a decreased serum phosphorus, and an increased blood phosphatase. The excretion of calcium in the urine is also increased.

Hemangioma

This rare tumor occurs usually in the spine or in the skull. In the roentgenogram of the vertebra the appearance is honeycombed and may show collapse and wedging of the body. It must be distinguished from an ordinary compression fracture. This tumor responds to roentgen therapy. Occasionally it occurs in a long bone.

Solitary Cyst of Bone

Solitary cysts of bone occur typically in the metaphysis and adjacent diaphysis of long bones before the related epiphysis has closed and thus usually before the age of 20 years. The x-ray appearances are similar to those of giant cell tumor, but this usually occurs after the age of 20 and involves the epiphysis itself. Some authorities believe that the two conditions are closely interrelated.

The solitary cyst may be simple or multilocular. The exact causation is unknown, but the cyst may arise as a result of a metaphyseal hemorrhage or as the result of an attenuated central bone abscess.

The patient seeks help most frequently for a fracture which has occurred through the cyst. The common sites of involvement are the upper end of the humerus and upper end of the femur.

Treatment.—A considerable proportion (c. 50%) are cured by the healing process after the pathologic fracture. If the cystic changes persist or extend after fracture or are found on x-ray examination for pain, operative treatment is indicated. This consists of removal of an adequate area of compact bone to expose the cavity, thorough curettage of the wall, and cauterization with saturated solution of zinc chloride followed by packing with cancellous bone chips. Protection of the area by immobilization in plaster is required until the x-rays show consolidation. X-ray treatment is best avoided because of the possibility of damage to the epiphysal plate.

Eosinophilic Granuloma

There are a number of lesions of the skeletal system which are believed to have reticuloendothelial elements in them, namely, *Gaucher's disease*, *xanthomatosis*, *eosinophilic granuloma*, and *Letterer-Siwe disease*. The etiology remains unknown.

Eosinophilic granuloma affects chiefly older children and adults. The granuloma may be of the soft parts or of the bone. The disease is insidious with possibly a low-grade fever and some pain. Pathologic fracture may occur. Diagnosis depends on biopsy. Excision with bone replacement or radiation is the recommended treatment.

Osteitis Deformans (Paget's Disease)

This is a generalized disease showing a thick and enlarged skull, bowing of the legs, and changes in other portions of the skeleton. It affects adults only. The disease does not shorten life significantly unless sarcomatous changes in one of the involved bones occur.

The affected bones show enlargement with changes in contour. The bone and marrow show areas of degeneration and areas of attempted repair.

The serum calcium and phosphorus are normal, and the serum phosphatase is consistently elevated and appears to parallel the skeletal involvement and activity as shown by roentgenographic examination.

Polyostotic Fibrous Dysplasia

This is a rare disorder showing a regressive metaplasia of bone into fibrous tissue. In those affected, precocious puberty is frequent in females, but the sexual development of males is normal. The disease begins in childhood of unknown cause. Some of the cases show cutaneous nevi. The progress of the disease may be slow or rapid, and pathologic fractures may be produced.

The entire skeleton should be examined roentgenographically, and if doubt in diagnosis exists, biopsy is done. There is no cure for the basic disorder. Pathologic fractures are to be treated with braces or splints, and bone graft replacements should be considered.

PRIMARY MALIGNANT TUMORS OF BONE

These are found chiefly in the younger age groups. They are relatively rare in comparison with other malignant growths and can present many difficulties in diagnosis to the roentgenologist, pathologist, and surgeon. Successful treatment of bone sarcoma, as in other types of malignant lesions, depends upon early diagnosis, the type of tumor, and to some extent on its location.

Osteogenic Sarcoma

This is the most malignant and most common bone tumor. Mayo Clinic statistics show that in 75% of cases, osteogenic sarcoma oc-

curs about the knee. Most cases occur between 10-20 years of age and slightly more in males than in females. The metaphysis of the lower end of the femur or that of the upper end of the tibia is usually involved, other sites being upper end of humerus, upper end of fibula, pelvis, and scapula.

Symptoms and Signs.—Pain, at first intermittent and then continuous, is the chief symptom. It may be accompanied by a limp, and later swelling may be seen. The diagnosis must take into consideration many factors,

The alkaline phosphatase is increased in osteogenic sarcoma. Osteogenic sarcoma metastasizes by the blood stream to the lungs and to other bones.

Histology.—The microscopic picture is most variable in this lesion. Spindle cells predominate, especially in the more malignant types, and occasional giant cells are present. The intercellular substance may consist of mixtures of cartilaginous, myxomatous, osteoid, osseous, fibrous, and hyaline tissue.

Fig. 702.—Osteogenic sarcoma involving the upper shaft of femur, showing the radiating spicules of bone and raised periosteum in anteroposterior and lateral views

history, physical examination, roentgenogram of tumor and of chest, laboratory examination, surgical biopsy, and previous treatment. Microscopic examination of the tissue is the most valuable aid, but this may also be difficult if the tumor has been previously irradiated or if infection has occurred from a previous biopsy. Laboratory examinations should include urinalysis, hemogram, and blood Wassermann

X-ray Features.—These vary somewhat, depending upon whether the tumor is osteolytic or osteoblastic. Early, the x-rays show an area of bone destruction in the subcortical zone extending outward. Strands of new bone formation are seen with raising of the periosteum but no expansion of the cortex. The new bone is frequently laid down as radiating spicules at right angles to the shaft.

Treatment.—Amputation is usually the preferred treatment. Partial amputation or resection has been considered for some cartilaginous tumors in the distal end of an extremity. Osteogenic sarcoma in children may be radio-sensitive, and x-ray may be used as a pre-operative treatment. X-rays of the lungs should always be taken before surgical removal is undertaken.

Site of Amputation.—One must decide whether to do the amputation through the bone affected above the tumor or through the bone proximal to the bone affected. When amputation is through the bone affected above the tumor, a section should be made from the end of the bone removed, and if malignancy is present, amputation above the joint or disarticulation is indicated. If pulmonary metas-

Fig 703—Fibrosarcoma of the lower femur. This lesion appears to be arising from the medullary portion of the bone and is usually of low-grade malignancy. This patient had symptoms of pain and dysfunction for more than a year and was treated by amputation. Microscopically the picture was of malignant fibroblasts with some pleomorphism.

Fig 704—Ewing's endothelioma of the femur.

tases are already present, no surgery should be done, unless for palliative reasons, e.g., to remove a useless leg or for pain.

Chondrosarcoma

This tumor appears in adolescence and early adult life. It occurs chiefly at the lower end of the femur and upper end of the tibia. The tumor consists of cartilage, connective tissue, and bone derived from malignant tumor cells.

Treatment.—Biopsy should first be done. If the diagnosis is confirmed, early amputation is necessary.

Endothelial Myeloma (Ewing's Sarcoma)

This tumor is found in children and in young adults. The shafts of long bones are most commonly involved, but occasionally the jaw and small bones are also affected.

Fever is a frequent sign of Ewing's tumor and not of other bone tumors. The differentiation between this tumor and osteomyelitis has always been difficult but is more so if anti-

Fig. 703.—Reticulum cell sarcoma of pelvis and femur. This bears considerable resemblance to Ewing's tumor, although in general it occurs at a slightly older age and is extremely malignant and very radiosensitive. It can usually be differentiated only microscopically.

A secondary type of chondrosarcoma may arise from a pre-existing osteoma, chondroma, or Paget's disease. Biopsy for confirmation should be performed. If microscopy discovers sarcoma, amputation is justifiable in the absence of pulmonary metastases.

biotic or preliminary x-ray therapy has already been given. The sedimentation rate may be raised in these cases, but the leukocyte count is not usually as high as in cases of osteomyelitis.

The diagnosis is to be made by biopsy and microscopic examination.

The structure of the tumor is semisolid and of a grayish white color with areas of hemorrhage. The tumor extends along the medullary canal as well as through the haversian canals to the surface of the bone. The inner layers of bone are destroyed while new layers of bone are deposited on the outside, described as "onion layers" in the x-ray picture.

The common sites are the shafts of the long bones (tibia, humerus, femur, fibula). The os calcis is the most frequently involved small bone.

Treatment.—This is one of the most radiosensitive of all tumors, and x-ray therapy should always be given after the diagnosis has been established. This usually results in diminution of the tumor, but secondary deposits are common. Amputation of the affected limb following a course of irradiation is generally preferred. This should be done through the bone proximal to the affected bone, if possible. Resection of certain bones, e.g., fibula, ulna, or scapula, is possible if the tumor is present. The metastases of Ewing's tumors are

Fig 706—Multiple myeloma of pelvis and upper femur

Histology.—Small round and polyhedral cells are arranged in solid masses. The intercellular stroma is scanty. The picture may be obscured by degenerative changes or previous irradiation.

X-ray Features.—Central rarefaction of a patchy type with sclerosis of the cortex and "onion peel" new bone are characteristic.

also radiosensitive and are frequently found in other bones (skull, sternum, vertebrae). Pulmonary metastases are common.

Multiple Myeloma (Plasma Cell Myeloma)

This tumor is being diagnosed with increasing frequency though formerly it was considered a rare disease. It occurs chiefly in

adults 40-60 years of age and is almost twice as common in males as in females. The origin of the tumor is from the hematopoietic cells of the bone marrow and involves chiefly the spine, pelvis, skull, ribs, and proximal long bones in multiple locations.

Multiple myeloma usually manifests itself by pain, especially in the back and thorax, by weight loss, and by pathologic fractures which are common.

X-ray Features.—There is bone destruction without compensatory new bone formation. Early cases may show only a diffuse osteoporosis, later the trabeculae and cortex are destroyed and appear as multiple clear punched-out areas.

Diagnosis.—(1) Bone marrow biopsy of the sternum or of the actual lesion shows typical round or oval cells with eccentrically placed nuclei, arranged diffusely without intercellular substance. (2) Bence Jones protein is present in the urine in about 50% of the cases. (3) Hyperproteinemia, usually of the globulin fraction, is present in approximately 60% of the cases. (4) Uric acid may also be elevated in some cases and is probably a reflection of the nucleoprotein catabolism of the myeloma cells.

Treatment.—An occasional solitary lesion has been excised, with complete relief, but it is more usual for the solitary lesion to show multiple involvement at a later date. The main treatment is palliative and includes deep x-ray therapy or urethane for the relief of pain, together with general supportive measures. The disease is usually fatal in 2-3 years.

SECONDARY MALIGNANT TUMORS OF BONE

Metastatic deposits of carcinoma occur in bone from primary carcinoma in any tissue but are chiefly from carcinoma of the breast, prostate, thyroid, kidney, and bronchus. The spine, humerus, and femur are most frequently involved. Pathologic fractures are common in the metastases from the breast, thyroid, and kidneys but rare in those from the prostate.

X-ray Features.—The bone appears mottled due to the localized destruction. There is no periosteal reaction.

Treatment.—The prognosis is hopeless, but pain can be relieved and prolongation of life secured by irradiation. Pathologic fractures are to be immobilized for the relief of pain, and the fracture sometimes unites.

Fig 707—Secondary carcinoma involving the upper shaft of femur, a metastasis from carcinoma of the breast.

TUMORS OF JOINTS

These may arise from the structures within the joint or secondarily invade the joint when the primary neoplasm arises in the periarthral tissues.

The benign tumors are *lipoma*, *fibroma*, *hemangioma*, *xanthoma*, and *endothelioma*.

Wide resection of the tumor is indicated. When complete synovectomy is required, motion is usually restricted by 25-50%. If the hemangiomatous lesion is diffuse, roentgen therapy is indicated.

Synoviorrhiza is the most common malignant tumor. It is a disease of young adults and is believed to arise from a specially differentiated

type of mesodermal cell. Microscopic examination shows fibrous septa that enclose masses of spindle-shaped or polyhedral cells. The cells may line irregularly shaped spaces. Metastasis usually occurs by the blood stream. The diagnosis is made by biopsy and is followed immediately by a high amputation. The prognosis is poor, especially in the older age group.

Chapter 43

Disorders of the Vertebral Column

Albert A. Butler, MD.

ANATOMIC CONSIDERATIONS

The vertebral column consists of 33 vertebrae; they are named in regions. There are 7 cervical, 12 thoracic, and 5 lumbar vertebrae which are movable. There are 5 sacral, fused in the adult to form the sacrum, and 4 coccygeal fused to form the coccyx. The total number of vertebrae is almost constant, but regional variations frequently occur. As one would expect, we often see transitional vertebrae which have some of the characteristics of two regions. Thoracic vertebrae show most of the common characteristics, but each region has its special form. The 1st and 2nd cervical are entirely individual. The usual parts of a vertebra are the body, the pedicles, the superior and inferior vertebral notches, the laminae, the vertebral arch, the vertebral foramen which is bounded by the vertebral arch and the back of the body, the spinous process, and the transverse processes, the superior and inferior articular processes which project upward and downward from the junction of the pedicle and lamina and have smooth surfaces for articulation with the contiguous vertebrae. In the vertebral column the vertebral foramina form the vertebral canal. The vertebral notches with the articular processes, bodies and discs, form a series of intervertebral foramina for the emergence of spinal nerves and vessels.

Cervical Vertebrae

(See Plate 107.)

Cervical vertebrae are small and show three foramina—the large vertebral foramen in the middle and small ones in each transverse process. The pedicles are short, the laminae are long, the spinous process is short and bifid, and the transverse process, enclosing a foramen, ends in an anterior and posterior tubercle. The 1st cervical vertebra, or *atlas*, has no body and no spinous process. It is formed by a pair of lateral masses united by an anterior and a posterior arch. There is an anterior tubercle for the attachment of ligaments, and the transverse processes are large for the attachment of the muscles that rotate the head. The 2nd cervical vertebra, or *axis*, is characterized by the odontoid process which articulates with the anterior arch of the atlas. The spinous process is strong and broad and bifid, whereas the transverse process is small and not bifid.

Thoracic Vertebrae

Thoracic vertebrae have facets on the bodies for articulation with the heads of ribs and most have facets on the transverse processes for the tubercles of ribs. The bodies are large, the laminae are broad, each overlapping the lamina below, the vertebral foramen is circular, the spine is long and slender, and the transverse processes are thick.

Lumbar Vertebrae

(See Plate 108)

Lumbar vertebrae show a large body, the pedicles are short and strong, the laminae are thick, and the vertebral foramen is large. The spinous process is almost horizontal, and the transverse processes are long and slender. The articular processes are large, the superior ones being concave, facing medially and the inferior, convex, facing laterally.

Sacral Vertebrae

The sacral vertebrae, 5 in number, are fused to form the sacrum, which is triangular in shape. The base is directed upward and forward, and its projecting anterior part is called the promontory. Behind the fused bodies the vertebral foramen leads into the sacral canal. The fused lateral masses form the ala of the sacrum, spreading laterally from the body. The apex is formed by the small lower surface of the body of the 5th sacral vertebra.

Coccygeal Vertebrae

The coccygeal vertebrae vary in number from 3-5 and are fused to form the coccyx, which is triangular in shape, with its base proximal and its apex distal. It consists of the rudimentary bodies of the vertebrae, more often fused than not but commonly irregular in shape.

Ossification of Vertebrae

The typical vertebra has three primary centers. One appears in each body of the lower thoracic region at about the 10th week, and two centers appear in the bodies superior and inferior to this region until present in all bodies by the 20th week, except the lower sacral ones which appear at the 30th week and the coccygeal ones which appear after birth. Two appear at the bases of the superior articular processes in the upper cervical region about the 7th week. This process extends downward, reaching the sacrum about the 20th week. Ossification extends from these two centers into the vertebral arch, processes, and lateral parts of the body. The central and lateral parts of the body begin to unite about the 3rd year

in the neck, and the process is complete in all regions by the 7th year. Laminar ossification is completed after birth, first in the lumbar region, extending upward and downward, becoming complete in the cervical at the 15th month and in the sacral about the 10th year. After union of the laminae, ossification extends into the spinous processes.

Five secondary centers appear at puberty and unite with the rest of the bones by the 25th year. There is one for the tip of the spinous process, one at the end of each transverse process, and an annular one on the upper and lower surface of the body.

Joints of Vertebral Column

The bodies of movable vertebrae are united by fibrocartilaginous discs, aided by longitudinal ligaments. In the cervical region there are also capsules of small synovial joints between their lateral parts. The articular processes are united by capsules of synovial joints. The vertebral arches are united by the intertransverse, interspinous, and supraspinous ligaments and ligamenta flava. The intervertebral discs are attached firmly to the articular cartilage which is seen on the contiguous surfaces of the bodies. The disc forms a dense annulus fibrosus in the periphery and softens toward the center, forming the nucleus pulposus. In the cervical region they do not reach the posterolateral edges of the bodies, due to the presence of small synovial joints. The anterior longitudinal ligament is thick and strong, extending from the anterior arch of the atlas to the sacrum, attaching to the fronts of bodies and to the intervertebral discs. The posterior longitudinal ligament lies in the anterior wall of the vertebral canal, from the axis to the sacrum, attaching to the backs of the bodies and to the intervertebral discs. The ligamenta flava are strong elastic sheets that connect the laminae of contiguous vertebrae, laterally blending with the synovial joint capsule. The interspinous ligaments are attached to adjacent spines from base to tip, and the supraspinous ligaments form a long continuous band connecting the tips of the spinous processes along the whole length of the vertebral column. This is thickened in the neck to

form the ligamentum nuchae, of importance because of its occipital and muscular connections.

The Vertebral Column as a Whole

The vertebral column may be considered as a central post for support of the body with a complex arrangement of its component parts, supported by strong ligaments and powerful muscles. There are four normal curves, two with their convexities forward in the cervical and lumbar regions and two with their convexities backward in the thoracic and sacral regions. These are smooth curves with a moderate variability within the range of normal, beyond which they are considered pathological, named *lordosis* and *kyphosis*, respectively. The posterior aspect of the vertebral column should present a straight vertical line, or just a trace of right thoracic curve being considered within the normal limit. Any appreciable curve is considered pathological, named *scoliosis*, and designated right or left with its region, according to the side of the convexity. There are, of course, variations with age. The child does not assume the normal curves until he is standing and walking. In old age there is a tendency for the spine to assume a smooth posterior curve throughout. Movements of the spine are carried out by a complex interaction of the enveloping musculature. Flexibility is provided by the compressibility of the intervertebral discs and the gliding action of the synovial joints. The greatest stability is in the erect posture, by virtue of the interlocking articular processes. In the cervical region anteroposterior movement is freely carried out. Lateral flexion is only possible by a combination of torsion and rotation of the vertebrae. In the thoracic region anteroposterior movement is greatly limited by the vertical position of the articular processes. Lateral flexion is much freer, and there is quite a good range of rotation. In the lumbar region flexion is very free, whereas true rotation is negligible. The apparent movement is a combination of flexion and circumduction. Alterations from the normal range of appearance and function range from postural defects to traumatic and diseased processes.

Dehydration of Nucleus Pulposus.—At an early age fibrocartilage invades the nucleus pulposus and there is an associated loss in water content with consequent reduction of its resilience. This causes an irregular distribution of stress, which also occurs when the nucleus protrudes through the hyaline cartilage plate or through the annulus fibrosus. The anterior portions of the bodies have less support than is found posteriorly, because of the presence of pedicles, and therefore show more involvement.

Adolescence.—Increased pressure anteriorly causes retardation of growth, fragmentation of the epiphyseal ring, and wedging of the vertebrae. This is called *Scheuermann's disease*.

Adults.—Reduced efficiency of the discs results in reactive new bone formation with peripheral osteophytosis especially marked laterally. Osteophytes are evidence of disc degeneration but do not necessarily produce symptoms. In senility, the discs may ossify peripherally, fusing the bodies, with wedging of the vertebrae as seen in senile kyphosis. If the vertebrae are atrophic and the discs relatively normal, the discs may expand symmetrically as seen in radiologic studies of senile osteoporosis.

Hyaline Cartilage Plates.—Damage to the hyaline plates may permit the nucleus to enter into the bone of the vertebral body, which reacts by producing a ring of sclerosis around the intruded nuclear material. This may be demonstrated by x-ray, and such a lesion is called a *Schmorl's node*.

Adults.—Damage to the hyaline plate permits the nucleus to enter the bone, but it is not walled off as occurs in adolescence. Instead, trabecular absorption takes place and collapse follows. This is seen when the x-rays at the time of injury are normal but subsequently show collapse and wedging of the vertebral body. This traumatic disorder is known as *Kummell's disease*.

Annulus Fibrosus.—Injury to the annulus permits early or late extrusion of the nucleus and causes symptoms characteristic for the region involved. In the cervical region it is common to find radiation with occipital headaches and interscapular, shoulder, and arm

pain In the thoracolumbar region it may give rise to radiating pain simulating visceral disease. In the lumbosacral region it is the commonest cause of sciatica

BACK PAIN

Back pain is a common symptom in a multitude of disorders, and careful assessment is always necessary. There is a considerable divergence between severity of pain and objective findings. Often there are severe symptoms in the early stages of a lesion when objective findings are elusive, or again there may be gross objective signs of disorders which are well compensated for and therefore do not give rise to much pain. The former are frequently labelled psychosomatic disorders when in fact there is a definite organic lesion which could be recognized on more careful examination. Positive x-ray findings are often of great value, but it must be remembered that the vertebral column is largely composed of cancellous bone, and reactive changes must be extreme before a radiologic diagnosis can be made.

A complete medical history is important. This must be correlated with a detailed description of the spinal symptoms from time of onset throughout periods of remission and exacerbation, their relationship to bed rest, sitting, walking, lifting, straining, twisting, and other activities, effect of the weather, the menstrual cycle, and relationship to other illnesses.

Physical examination should be carried out with the patient undressed or with a minimum of underclothing. A complete routine should be followed, noting positive and negative findings. This examination should elicit body type, muscular development, general posture, deformities, location of tenderness or pain and its radiation, all movements of the spine and extremities, with reflex, motor, and sensory testing, and with abdominal and rectal examination. The patient is examined standing, sitting, lying supine, and lying prone.

In scoliosis, flexion accentuates a structural curve but causes a postural one to disappear. In Pott's disease localized tenderness, spinal rigidity, and an angular kyphosis may be noted. Hyperextension tests the hip and sacroiliac and

lumbosacral joints, being positive according to location of pain. Rotation or lateral compression of the pelvis strains the sacroiliac joint and may indicate a disorder there. Straight leg raising is limited in sciatica, and the pain is further aggravated by dorsiflexion of the foot (Lasègue's sign). Short hamstrings cause a painless limitation of straight leg raising, and dorsiflexion of the foot is not painful. Joint crepitus is most easily elicited with forced rotation in the cervical region and may indicate osteoarthritis in the facet articulations. Clicking of the hip or sacroiliac or lumbosacral joint may be a normal variant or of clinical significance.

It is usually necessary to supplement the examination by radiologic studies of the region clinically indicated. Hemograms, blood chemistry, and other tests may be required, depending on one's provisional diagnosis.

Classification of spinal disorders is an aid to diagnosis and should be both anatomic and etiologic.

1 Developmental or Congenital Defects

- Hemivertebrae

- 6 *Neoplastic Disorders of the Vertebral Column*

DEVELOPMENTAL OR CONGENITAL DEFECTS

The most frequent congenital anomaly of the vertebral column is spina bifida. (See

Hemivertebrae

The segments of cartilaginous vertebrae in the embryo may fail to unite, and two centers of ossification appear instead of one. Different rates of growth in the two segments may give rise to a congenital scoliosis; persistence of the separation between the two segments may be followed by an anterior spina bifida. Development in one segment only produces a true

hemivertebra, resulting in a sharp lateral curvature of the spine.

Synostosis

If two adjacent vertebral bodies fuse during their development, a synostosis or congenital block vertebra results. The Klippel-Feil syndrome is a synostosis of lower cervical vertebrae, associated with spina bifida, producing a short and rigid neck. Occipitalization is a synostosis of the atlas with the occiput. Sacralization is a fusion of the 5th lumbar with the sacrum.

be of no consequence, but approximately 20% of them do show some pes cavus deformity or other neuromuscular anomaly of the lower extremities. Often there is limitation of straight leg raising, due to shortening in the hamstring muscles, and often there is an equinus of the foot or at least a limitation of dorsiflexion, due to shortening of the calf muscles.

Spondylolysis

This is a defect in the neural arch, occurring between the facet articulations. With this defect in the pars interarticularis there is only soft

Fig. 709—Synostosis of lower cervical vertebrae

Spina Bifida Occulta

Spina bifida occulta as opposed to the true spina bifida shows little or no neurologic involvement. There is usually a defect in the neural arch of several vertebrae, the commonest location being in the lumbosacral region. Brailsford gives an incidence of 6% in the 5th lumbar and of 11% in the first two sacral segments. These defects are commonly stated to

tissue stabilization at this level of the spine. Displacement is accompanied by soft tissue separation at the defect, as well as at the intervertebral disc, and associated ligaments. It may produce a traction lesion by the nerve roots being dragged against the vertebral notch. This displacement is known as spondylolisthesis and is commonest in the 5th lumbar vertebra.

Fig. 710.—Spondylolysis showing defect in pars interarticularis

Fig. 711.—Spondylolisthesis showing displacement at the pars interarticularis

Spondylolisthesis

In spondylolisthesis 90% of the defects occur at the 5th lumbar, most of the others involve the 4th lumbar; they are rarely seen elsewhere. In some the displacement occurs soon after birth. Freiberg believes that most of the displacements occur about 12 years of age. Undoubtedly, many do not occur until there is some unusual stress on this segment of the spine. This might follow heavy weight lifting,

of slipping occurring during certain movements. The most extreme spondylolisthesis seen showed lumbar 3, 4, and 5 lying in front of the sacrum. There was no evidence of neurologic involvement; in fact, the patient refused treatment once his curiosity was satisfied as to why his ribs were resting on the pelvis. It is usual, however, for the displacement to be less than a complete dislocation. Traumatic spondylolisthesis, as a major hyperextension injury

Fig. 712—Spondylolisthesis showing forward displacement at L5-S1

or some illness with muscular impairment, or obesity with loss of muscular power after giving up athletic activities. Adaptive changes in the shape of the vertebral body would serve to indicate that the displacement had occurred during the growth period. Both spondylolysis and spondylolisthesis commonly give rise to the symptoms that we associate with ligamentous strain. It is not unusual for them to be entirely symptomless by virtue of adaptive changes in the ligaments and compensation by powerful muscle control. Most of the displacements are rigid in their position of deformity, but occasionally a good deal of instability can be demonstrated, and the patient may be conscious

producing a fracture-dislocation along the same path as the usual congenital defect, is a rare occurrence.

Clinical Features—The majority of patients do not complain of symptoms until well into adult life. It is often difficult to determine just when the displacement did occur. Usually they give a history of some fairly recent injury, to which they attribute their trouble. They are often incredulous when told that it is congenital in origin. Pain is not constant but is associated with certain movements, particularly stooping and lifting. Usually there are no neurologic changes, but occasionally a typical

sciatic syndrome is present. When the displacement is appreciable, there is a sharp depression above the 5th lumbar spinous process which is increased with hyperextension. The lumbar region may appear shortened and the sacral region appear lengthened. If there is marked displacement in a pregnant woman, it may constitute an obstruction to normal delivery. The condition is most clearly seen in oblique x-rays, although if there is significant displacement, it is well seen in the lateral view.

Treatment.—Many of these patients are free of symptoms, due to the natural compensation of powerful musculature. It is not surprising, therefore, that many of those who do have symptoms are relieved by exercises which develop the erector spinae. Strain also is reduced by development of the hip extensors, enabling them to diminish the pelvic inclination and flatten the lumbar lordosis. These measures may be aided by the use of a lumbosacral corset or brace, which reduces the painful movements. If pain is severe, or if freedom from restrictive measures is desired, or if there is increasing displacement, spinal fusion is indicated. Reduction of the displacement may be obtained, when it has occurred recently, by the method described by Watson-Jones. This consists of vertical traction on the flexed hips with the shoulders resting on a table, so that the pelvis is drawn forward against the body weight, if necessary supplemented by the downward traction of a sling around the abdomen. If correction is obtained, a plaster spica is applied and posterior spinal fusion carried out through a window in the cast. In the presence of a rigid deformity, operative reduction is a formidable procedure and is not worth while. Spinal fusion should be carried out in the position of deformity. Anterior fusion of the 5th lumbar body to the sacrum by an abdominal approach appears mechanically preferable, but the mortality rate has been excessive. Posterior spinal fusion is considered the method of choice. The area of fusion is subjected to a good deal of shear. Therefore the method used should produce a massive area of fusion, and it should be protected until it is mature. This reduces the very real risk of pseudarthrosis. The complete Hibbs procedure, with excision of the interarticular joints, and the loose vertebral arch and the fibrous masses over the nerve roots, sup-

plemented by a massive "H"-shaped iliac graft, seem to fulfill these requirements.

Kissing Spines

This is a developmental variation in which there is contact between deformed spinous processes, giving rise to pain, and usually limitation of extension of the spine. An x-ray of the spine which gives good detail in the vertebral body region does not show the spinous processes so well and requires close inspection. There may be a false joint or condensation of bone at the points of contact. A similar condition is seen as a complication of spinal fusion. If the surgeon fails to preserve the soft tissue between the spinous processes at the limits of his fusion, then the graft or subsequent callus may impinge on the adjacent spinous process with spinal movements and give rise to pain of the same type. A cure of both conditions is simply to excise the offending bony protuberance and suturable soft tissue between them.

Sacralized Transverse Process of the 5th Lumbar Vertebra

This is a congenital variation from the normal, in which there is enlargement of one or both transverse processes. It (or they) articulates with the sacrum or sacrum and ilium. The term transitional vertebra is used to indicate that it has some characteristics of both lumbar and sacral segments. Often the articulation is structurally poor and suffers traumatic or degenerative change readily. This will produce pain on the same side. Commonly, however, pain is on the opposite side. This is probably due to strain on the weaker side. With movement to the side of the bony buttress there may be leverage against the ligaments on the opposite side. This would produce recurrent ligamentous injury. The 4th lumbar nerve passes over the prominent transverse process. With spinal movement may give rise to a traction lesion. If the enlarged transverse process is just short of articulating with the ilium, it may, with spinal movement, give rise to intervertebral soft tissue and give rise to traumatic inflammatory changes. It could also produce an adventitious bursa, with recurrent bursitis.

Cases have been described in which osteophytes from an arthritis in the false joint have encroached on the intervertebral foramen, affecting the emerging nerve root. The counterpart of this syndrome occurs with lumbarization of the 1st sacral segment. One must recognize that this anomaly may be present but the symptoms are due to one of the other numerous causes of low back pain. For instance, the intervertebral disc immediately above is rendered more vulnerable and may be the lesion requiring treatment. Thorough investigation is essential.

5. The maintenance of powerful musculature by daily remedial exercises is designed to prevent recurrences.

Operative.—Indicated if adequate conservative treatment fails or if heavy use of the back is necessary.

1. *Transversectomy* is indicated if one is certain this anomaly accounts for the symptom complex. It allows early mobilization of the spine with a short convalescence.

2. *Spinal fusion* is often preferable as it strengthens the spine. It will also cure the

Fig. 713.—Sacralized transverse process of 5th lumbar vertebra

Treatment.—

Conservative —

1. *Bed rest* is indicated at the start of an acute exacerbation of symptoms.

2. *Limitation of painful movement* is achieved with a Harris brace or a plaster corset.

3. *Novocain infiltration* is often of diagnostic and therapeutic value.

4. *Deep heat, massage, and exercises* are used as the acute phase subsides.

symptoms of almost any low back disorder associated with this condition.

Cervical Rib and Scalenus Anticus Syndrome

(See Chapter 11, Neurosurgery, and Chapter 33, Peripheral Vascular Diseases.)

Congenital Torticollis

There are many causes for *wryneck*—hysterical, habitual, ocular, bony, muscular, and nerve lesions. It may be associated with con-

genital, paralytic, traumatic, or inflammatory changes

The congenital variety is due to a retardation in lengthening of the sternomastoid muscle. The disturbance is probably due to interference with the arterial blood supply—analogous to a Volkmann contracture.

Clinical Picture.—Soon after birth a firm lump may be felt in the sternomastoid. This disappears spontaneously, but an observant mother may notice that there is some restriction of neck movements. Gradually a deformity develops due to the related shortening of the muscle. There is a flexion of the head to the

Conservative treatment consists of passive stretchings. The mother is trained in the technique and carries it out three times daily. Clinical review is essential at frequent intervals. It should be discontinued unless effective.

Operative treatment is indicated with the appearance of any appreciable deformity. The sooner it is done the better. It consists of an open division of the sternal and clavicular heads of the sternomastoid muscle. Postoperative splintage in the overcorrected position is used till soft tissue healing is consolidated. This is followed by postural exercises and passive stretchings. Review at suitable intervals up to

Fig. 714—Congenital torticollis

side of the lesion and a rotation of the face to the opposite side. If the condition is not treated, asymmetry of the face develops. There is ocular adjustment to the position of deformity. This becomes a problem in late corrections. There may be secondary structural changes, giving rise to an upper thoracic scoliosis and elevation of the shoulder. These changes constitute a very ugly deformity. Double torticollis and posterior torticollis are rare. The latter is due to similar changes in the trapezius and other posterior muscles.

Treatment.—It appears that some infants develop the lump in the sternomastoid muscle and go on to complete and spontaneous recovery. If, however, any of the other signs develop, it is imperative to commence early treatment.

adolescence is advisable. Any recurrence should be prevented or corrected before it develops into a real disability.

POSTURAL DEFECTS

Postural defects are those which cannot be attributed to any traumatic or disease process and which can be corrected by voluntary efforts. They are often associated with postural defects elsewhere in the body. Form and function are interrelated, so that during the growth period a postural defect may be converted into a structural one. Also, conversely, during the growth period minor structural defects may be corrected by the development of a good posture. While in the adult the plasticity of bone is not entirely lost, these changes be-

come negligible. The natural tendency, nevertheless, to compensate for a structural defect can be enhanced by the development of powerful musculature. The maintenance of a poor posture is probably a function of the central nervous system. A habit produces a conditioned reflex, which maintains the altered muscle length as if it were normal. It is common to have weak muscles associated with a faulty posture, but this is not necessarily so. The conscious effort to maintain a correct posture until it becomes a conditioned reflex is probably the most important feature in the treatment

the hip flexors and decreased by the hip extensors, any alteration affecting the entire posture of the spine.

Lumbar Lordosis

Lumbar lordosis is a deviation from normal posture, in which the pelvis is tilted forward. In order to maintain the line of weight-bearing, it is necessary to have an increased concavity in the lumbar region. There is perhaps a little increase in the thoracic kyphosis, but this is not a prominent feature. The whole appearance is

Fig 715—Types of postural defects

It is apparent that any alteration in the weight-bearing joints may affect spinal posture. It may be a valgus foot with external rotation of the limb and tilting of the pelvis and therefore of the spine; or it may be primarily in the hip, pelvis, or the spinal column. There are various methods of measuring pelvic inclination, but the range of normal variation is wide enough to depend on careful observation. An instrument called a *pelvic inclinometer* permits a reading of pelvic inclination from the upper part of the symphysis pubis to the level of the posterior superior spines of the ilium. The instrument has two blades to be placed centrally at these levels and an attached protractor with a plumb line to give the reading. The inclination of the pelvis is increased by contraction of

altered by correcting the pelvic tilt, e.g., tightening the gluteal and abdominal muscles.

Sway-Back

Sway-back is a combination of forward tilting of the pelvis and a dorsolumbar kyphosis. In this disorder, instead of correcting the line of weight-bearing by increasing the lumbar concavity, the entire spine is bent backward, rather markedly at the lumbosacral level. The pelvis projects forward, with the body and the legs sloping backward.

Round Back

Round back is characterized by a decreased pelvic inclination in combination with a dorso-

lumbar kyphosis. With this, the line of gravity may be corrected by the trunk being held forward, producing obliteration of the lumbar curve. It may also be corrected by bringing the pelvis forward and angulating the trunk backward at the lumbosacral level, producing an appearance somewhat similar to the sway-back posture.

Fig. 716 — Fatigue posture (sway back).

Flat Back

The flat back is produced by the pelvic inclination being reduced and is balanced by a reduction in the lumbar curve. This type of variation from the normal is less noticeable than the others, but it does give rise to trouble in later life and should be corrected.

Round Shoulders

This is a mixed type of postural defect which the scapular muscles sag, allow shoulders to fall downward and forward further aggravated by some increase thoracic curve and forward inclination head and neck

Postural Scoliosis

This is a functional lateral curvature can be fully corrected by voluntary effort is in the same category as other postural defects and does not give rise to serious structural changes. There is usually a smooth transition of the lumbar and dorsal regions, with no rotation of the vertebrae and no secondary changes in the thoracic cage. The curvature appears when the spine is flexed. It soon disappears when sitting and can be corrected by muscular efforts when standing. It is intermittent and associated with fatigue. It is distinguished from the lateral curvature which occurs with a short extremity. Variations in leg length up to $\frac{1}{4}$ " are of no consequence and do not require correction. Children who show a postural scoliosis will usually correct it spontaneously with growth and muscular development. It is, however, wise to check on the child's general health and to teach postural exercises.

Treatment of Postural Defects.—On the mechanism of a postural defect is understood then the exercises necessary to correct it are easily determined. Advantage is taken of the reciprocal innervation of antagonistic muscle groups. If an extensor group of muscles is contracted in carrying out a movement, the opposing group relaxes sufficiently to permit the movement but contracts sufficiently to control the joint. If the extension is against resistance control of the joint is obtained between two forces, and the reflex inhibition of the flexors is much more profound. If, then, we wish to correct the increased pelvic inclination of a lumbar lordosis or a sway-back defect, we should develop the gluteal muscles and relax the hip flexors. Gluteal resistance exercises are therefore prescribed. If an exercise is carried out from a correct postural position and returns to this position, and is repeated

frequently enough, the normal postural reflex is re-established. It is not sufficient to simply build up muscular power by general exercises. It is important then to utilize the normal posture in all the daily activities, until it is finally maintained without conscious effort.

TRAUMATIC DISORDERS OF THE VERTEBRAL COLUMN

The complex arrangement of the vertebral column is susceptible to a wide range of injuries: muscular, ligamentous, discoid, cartilaginous, and bony, as well as neurologic. Pain arising in any of these structures may be referred to the skin distribution of the segmental innervation of the part concerned. It is accompanied by tenderness and muscular rigidity, and it is well to bear in mind the false localization and reflex muscular effects which may occur from the involvement of deep-lying somatic structures and also of certain viscera. Sciatica, for instance, may arise reflexly from a gluteal muscle lesion, a lumbosacral ligamentous lesion, or osteoarthritic changes in the facet articulations, as well as from direct pressure on the nerve root by protrusion of an intervertebral disc.

Myofascial Injuries

These injuries may produce a sciatic scoliosis with lumbosacral tenderness, occasionally tenderness along the course of the sciatic nerve, limitation of spinal movement (most marked limitation being of flexion), and limitation of straight leg raising. The attachments of the injured muscles are particularly tender, and there may be moderate tenderness over all of the muscle groups. The symptoms are relieved by heat and rest and are aggravated by activity. Novocain infiltration of the points of maximum tenderness is useful both as a test and for relief of symptoms. It is considered confirmatory when insertion of the needle aggravates both the local and referred pain, and the injection of the local anesthetic relieves both of these and is followed by the restoration of straight leg raising. Occasionally one sees systemic reactions, characterized by giddiness, rapid pulse, sweating, and a drop in blood pressure. If

severe, these symptoms may be relieved by the injection of 1 ml. of 1/1,000 Adrenalin. The antihistamine drugs are ineffective. Also, there may be a delayed painful reaction as the effect of the local anesthetic disappears, so that for a while the pain is far worse than the original one. This may be relieved by the use of analgesics. Treatment should have as its object the healing of damaged tissues with the prevention of extensive adhesions. Therefore, in the acute phase, rest and support of the part to relieve pain are indicated. Depending on the severity of symptoms, this may be achieved by strapping, a tight corset, a brace, or plaster jacket. Bed rest in the early stages is often advisable. Radiant heat and light massage are soothing in their effects. Short-wave diathermy and heavy massage will aggravate the condition, although they are often useful with active exercises as the acute phase subsides.

Chronic strain or improperly treated acute injuries may result in myofascial adhesions. They give rise to recurrent low back pain and sciatica, often with acute exacerbations. In some of these there is contracture of the gluteal fascia below the posterior superior spine. Roberts and Heyman have advised stripping of the posterior superior spine. In others, the contracture is more anterior in the tensor fascia lata and the iliotibial band. This may be demonstrated by the Ober test, which consists of having the patient lie on his good side and flexing the hips to flatten the lumbar spine. The affected leg is flexed to a right angle at the knee while the hip is steadied and then is abducted and extended, bringing the thigh in line with the trunk. The abduction contracture of the iliotibial band can then be felt as it maintains the limb in the abducted position. Ober has recommended division of the iliotibial band and fascia lata with the intermuscular septa for relief of this condition. When the original symptoms were due to involvement of the erector spinae muscles and there is no abduction contracture of the hip, manipulation of the spine is often recommended. Due, however, to the danger of displacing an intervertebral disc, this is considered a dangerous procedure. It also appears that in the vast majority of these conditions, an equally satisfactory result can be obtained by conservative measures. These consist of Novo-

DISORDERS OF THE VERTEBRAL COLUMN

Fig 717—Varieties of disc involvement as compared with the normal. The areas of lighter stippling connote osteoporosis.

cain infiltrations, massage, short-wave diathermy, and spinal exercises, sometimes supplemented by the use of a support.

Lumbosacral and Sacroiliac Strains

The ligaments supporting the lumbosacral and sacroiliac articulations are so powerful that it must be indeed rare to have an actual tearing of these structures. Ligaments, however, do not stand up well to continuous strain, and with muscular insufficiency and postural defects, they frequently give rise to symptoms. There is protective muscle spasm, with pain both local and referred, which may be present in varying degrees according to the severity of the strain. Usually there is relief of symptoms with bed rest, which continues into the morning, but the symptoms recur with the onset of muscular fatigue. A minor injury will often produce an acute exacerbation of the symptoms. Testing the joints while symptoms are present will produce an exacerbation, but often if examined in a period of remission, localization cannot be determined. The history of mechanism of injury may be of value, flexion injury being likely to affect the lumbosacral articulation, and twisting strains the sacroiliac joint. The latter is very powerful except during pregnancy, when, due to the hormone *relaxin*, the pelvic ligaments are relaxed. The sacroiliac joint may be tested by having the patient lie on his side and compressing the iliac crests, also lying on the back and forcing down on both anterior superior spines; or lying on the back, hyperextending one hip over the examining table. If positive, each of these tests reproduces pain and tenderness at the sacroiliac level. With the patient lying prone, hyperextension tests both joints, being considered positive according to the localization of the pain. Pain with flexion is often well localized in lumbosacral strains. Rotation tests are not very useful but, if positive, point to the sacroiliac joint. The vast majority of so-called sacroiliac strains are shown by these tests to be lumbosacral ones. Treatment is the same as described for myofascial injuries, except that Novocain infiltration is much less useful, and very occasionally for persistent cases a fusion of the affected joint may be required.

Intervertebral Disc Protrusions

There are two common regions for intervertebral disc protrusions to give rise to symptoms. The lower lumbar L4-5 and L5-S1 account for probably 90% of disc protrusions. The lower cervical C5-6 and C6-7 account for most of the others, the former being twice as frequent. There are many more symptomless disc protrusions than ones that give rise to trouble. Myelograms suggest a proportion of 4:1, but anatomic dissections suggest it is very much higher. It is obvious that a "proved disc" is not proof that it causes the symptoms. All other causes for the symptom complex must be considered in the clinical appraisal. There are many vertebral disorders in which some discoid anomaly is associated. These are described elsewhere in this section—see:

- 1 Spondylolisthesis
- 2 Pott's disease
- 3 Osteomyelitis of the spine
- 4 Hypertrophic spondylitis
- 5 Ankylosing spondylitis
- 6 Adolescent kyphosis
- 7 Senile kyphosis
- 8 Senile osteoporosis

The modern glib diagnosis of "disc" for almost every vertebral column disorder has, therefore, a grain of truth in it. It is, however, a retrograde development. The term should be reserved for the clear-cut symptom complex associated with extrusion of the nucleus pulposus or herniation of the annulus fibrosus into the vertebral canal, causing cord or nerve root irritation. The rarer nuclear prolapse or sequestered disc is likely to give rise to intractable nerve pain or cord symptoms and usually requires operative measures. The commoner, herniation of the annulus, is usually reversible, gives rise to intermittent symptoms, and responds to a variety of treatments.

Cervical Discs

If the protrusion is central and large enough, it produces a cord lesion resembling a cord tumor. Operative removal is imperative in order to prevent permanent damage. Fortunately these midline massive extrusions of the nucleus are rare.

Commonly the protrusion is lateral, and involvement of the nerve root is variable and usually reversible.

Clinical Features.—Some history of trauma, recent or remote, can usually be established. One would expect extrusion of the nucleus if symptoms were persistent from the time of injury. The vast majority of cases show a considerable time interval between the injury and the onset of symptoms. There is a predilection to the middle-age group, so that degeneration undoubtedly plays an important part. It is a traumatic degenerative change in a disc which has probably lost some of its resilience. The fluid content of an intervertebral disc decreases with age, and this dehydration is appreciable at about 40 years of age.

process at the involved level helps localization. The affected dermatome can be mapped out if there is objective sensory change.

A disc protrusion C5-6 is likely to produce sensory changes in the thumb and index finger. There may be loss in power of elbow flexion. The biceps jerk is diminished or absent.

If the involvement is at C6-7, the middle and ring fingers may show paresthesia. There will be loss of power of extension in the elbow, and the triceps reflex is diminished or absent.

X-ray examination may be normal in a recent involvement. When the condition has been present long enough for adaptive changes to occur, we expect to see narrowing of the intervertebral space. Often if films are taken in flexion and extension, an alteration in the

Fig. 718.—Cervical brace shown in anterior, lateral, and posterior views

Limitation of movement due to pain is seen early. There is referral of pain according to the segment involved. Jarring of the spine in any way is likely to aggravate symptoms. Maneuvers which increase cerebrospinal fluid pressure produce a sharp stab of pain, e.g., coughing, sneezing, and straining. There are troublesome subjective symptoms of numbness, pain, and coldness, before sensory involvement can be demonstrated. Muscular weakness may be detected by comparison of power with the unaffected limb. Tenderness of the spinous

curve can be detected. There is loss of mobility at the level of a disc lesion. Further progression will result in peripheral osteophytosis, and if this projects posteriorly, it is direct evidence of encroachment on the vertebral canal.

Treatment.—

Conservative.—It is generally recognized that a cervical disc protrusion responds well to conservative measures. These are as follows:

1. Short-wave diathermy and massage to relieve the secondary muscle spasm and pain

2 Analgesics and sedatives for the same reason

3. Head traction to reduce the herniation of the annulus; this may be by a small weight for a long period or a larger weight for short periods. A usual prescription is 20 pounds for 20 minutes, three times weekly for 3-4 weeks. Occasionally a 5-pound weight is used almost continuously for a week, in bed, and succeeds where the first has failed. A well-fitted head halter with ropes, pulleys, and weights is used.

4 Cervical splintage, this may be useful to limit painful movement, and there is a variety of methods: (a) plaster "doll's collar," (b) molded leather collar, (c) plastic mold collar, (d) high felt collar, etc.

dous interest in the subject since the early work of Mixter and Barr in 1934. Prior to that time the condition was not commonly recognized. It is probably now being diagnosed too frequently on insufficient evidence. The whole problem of low back pain must be understood in order to place the component parts in a proper perspective.

The lumbar discs at the lower two segments are subject to a good deal of stress, just as are the other structures at this level. When there is a nucleus pulposus extrusion, symptoms of nerve root irritation are usually severe and persistent. Bulging of the annulus fibrosus, which viewed from the vertebral canal aspect would give a washboard appearance, is often of much less importance. The former condition

Fig. 719—Harris brace shown in posterior, lateral, and anterior views. Especially used for lumbosacral lesions.

These measures should clear up symptoms in 90% of cases. Permanent relief is obtained by developing powerful cervical musculature and avoiding trauma to the region.

Operative—Operative treatment is as described for lumbar discs. The cord must be carefully protected and a careful technique is required.

Lumbar Discs

The involvement of lumbar discs is currently believed to be the commonest cause of low back pain. Certainly there has been a tremen-

ous interest in the subject since the early work of Mixter and Barr in 1934. Prior to that time the condition was not commonly recognized. It is probably now being diagnosed too frequently on insufficient evidence. The whole problem of low back pain must be understood in order to place the component parts in a proper perspective.

The lumbar discs at the lower two segments are subject to a good deal of stress, just as are the other structures at this level. When there is a nucleus pulposus extrusion, symptoms of nerve root irritation are usually severe and persistent. Bulging of the annulus fibrosus, which viewed from the vertebral canal aspect would give a washboard appearance, is often of much less importance. The former condition is not reversible, but the latter is often amenable to simple measures.

Clinical Features.—Symptoms fall into two main categories: those of gradual onset, which appear compatible with a degenerative lesion, and those of sudden onset, which suggest a traumatic lesion. Obviously, there are many variable factors and combinations of modes of onset. If there is a central protrusion, one finds bilateral involvement of the lower extremities, and the lesion may be at a higher level than expected. As localization clinically is

based on the level of nerve root emergence from the vertebral canal, a central protrusion may affect it a little higher up. The more common lateral disc protrusion is more accurately localized by the dermatome involvement. This is one of the many causes of the symptom complex referred to as *lumbago* or *sciatica*. It is probable that some cases with severe subjective complaints of this nature are minimal disc protrusions, but it is a speculative diagnosis which should not be made. Other more inclusive terms are more in keeping with the

and flexion of hip and knee on the affected side. Straight leg raising is limited on both sides but much more on the affected side. Lasègue's test is positive. It consists of flexing the knee and bringing the hip to a right angle. Then as the knee is extended, pain is produced short of full extension. If at this point the foot is dorsiflexed, there is further aggravation of the pain.

There is tenderness of the regional spinous processes, often maximal at the level of the lesion.

Hypesthesia or paresthesia should be mapped out and aids localization according to the dermatome pattern.

Muscle weakness is a common finding, particularly extensor hallucis longus in L3-S1 protrusions. The knee jerk is diminished or absent in L3-4 disc lesions, the ankle jerk in L4-5 and L5-S1 protrusions. This, however, is not entirely reliable. Due to variation in innervation, there is an error in localization in about 20% of individuals. Myelograms are also only accurate in about 80% of cases. However, when myelographic studies are correlated with the clinical findings, errors in localization are reduced to around 5%.

Rectal examination is done to exclude intrapelvic neoplasm as a possible cause for sciatica.

X-rays are of considerable value, both for confirmatory and exclusion evidence. There may be no changes in a recent protrusion, but later there is reduction of the interspace, perhaps loss of mobility in bending films, and possibly posterior osteophyte encroachment on the vertebral canal. Anteroposterior, lateral, and oblique films, at least, should be taken to help rule out congenital, infectious, and static disorders.

Myelogram is a special type of x-ray study in which 3-9 ml of Pantopaque are injected into the vertebral canal by ordinary lumbar puncture. By changing positions of the tilting table on which the patient lies, this can be gravitated as desired to outline the vertebral canal. Any encroachment by a disc protrusion is recognized by a filling defect. If the findings are compatible with the clinical picture, it is considered significant. Symptomless protrusions thus demonstrated are disregarded. The test is restricted to cases in which operative treatment is contemplated.

Fig 720 -The dermatomes of the leg (After Keegan)

probabilities and less likely to lead to misinterpretation. If there are motor, reflex, or sensory changes, then the probability of a protrusion is greater.

With *lumbago*, regardless of its cause, there is spasm of the erector spinae, flattening of the lumbar lordosis, and painful limitation of movement. In *sciatica* there is a scoliosis due to unequal muscle spasm in the lumbar muscles

Treatment.—**Conservative.—**

1. Short-wave diathermy, massage, and flexion exercises often suffice to clear up mild attacks.

2. Analgesics, sedatives, and local anesthetic infiltration of points of maximal tenderness aid the symptomatic relief.

3. Bed rest may offer a good deal of relief. Fracture boards under the mattress may give some firm support to the part. More often the

5. A Harris brace is useful to control chronic or recurrent attacks by limiting painful movement. It should be fitted with reduced lumbar lordosis.

6. A traction cast is probably the most effective measure. Traction of 50 pounds is used during the day and 20 pounds at night, until the acute symptoms disappear. This usually requires a week. Graduated activities in the cast are then permitted during the day as tolerated. The cast is retained for a further 5

Fig 721.—Traction cast with 50 pounds continuous traction

position of flexion, with pillows under shoulders and knees, gives relief by positional reduction of the tension on the sciatic nerve.

4. A flexion plaster corset is often effective. Lower lumbar flexion is obtained with the forward tilt of the pelvis when sitting. A cast applied in this position is worn for about 6 weeks. Exercises are started as soon as tolerated.

weeks, with traction being used only at night. (See Fig 721.)

Operative.—Operative treatment is indicated:

1. When the symptoms are so severe or persistent that it is thought conservative measures will be ineffective. The underlying lesions are usually sequestered nuclear protrusions or very large protrusions of the annulus.

2. When adequate conservative treatment has failed to give relief.

3. When motor, sensory, and reflex changes are severe enough to threaten permanent nerve damage.

4. When restrictions about the heavy use of the back cannot be accepted.

The localization is confirmed by Pantopaque myelogram

An interlaminar approach is used, and the offending disc is excised. Usually sequestration of the nucleus or adhesions of the annulus fibrosus herniation, as a result of delay in adequate treatment, accounts for the failure of conservative treatment.

Incomplete removal of the intervertebral disc is to be avoided, as it could result in a further protrusion and recurrence of the symptoms. It is wise to finish up with a localized spinal fusion, as the long-term results are better. The writer prefers the posterior spinal fusion by an "H" graft. This maintains the normal posterior

relationships of the adjacent vertebrae, making it unnecessary to enlarge the intervertebral foramina. (The nerve root lies in the inferior part of the intervertebral foramen directly between the intervertebral disc anteriorly and the capsule of the apophyseal joint with the ligamentum flavum posteriorly.) The graft is under physiologic compression, which, by eliminating shearing strains, encourages bony union. In fact if one could be certain that there was no sequestration of the nucleus pulposus or mature adhesions, the fusion by this method would alone reduce an annulus herniation and effect a cure. The objective of the operation is to produce a permanent cure of both the nerve lesion and joint derangement. If the lesion is at L4-5, it is advisable to include the vulnerable L5-S1 space as well; otherwise a second operation will be necessary at this level in an average of 5 years. When the derangement involves the L5-S1 space, however, fusion of L4-5 is not routine.

FRACTURES AND DISLOCATIONS OF THE VERTEBRAL COLUMN

J GORDON PETRIE, MD

Emergency Management.—First aid to the person with an injury to the back or neck is of prime importance and may influence the end result. It is now generally recognized that a patient with an injured vertebral column must be moved as a whole without allowing shift of the injured part. The first doctor to examine the patient should carry out an examination of the sensory and motor functions of the extremities; tenderness and deformity of the spinous processes can be quickly detected. If shock is present, it should be treated while other examinations are being done.

The serious cervical injury presents special problems. Temperature must be watched and hyperthermia controlled. Impaired respiratory function makes it important to maintain a free airway. Simple suction may be necessary, and oxygen may lessen cyanosis. Light longitudinal traction with an improvised head halter will provide safety in transportation.

The best method of transporting the victims of thoracic and lumbar spine injuries is on

a padded board the size of the ambulance stretcher and securely lashed to the litter. Hypothermia may be present and the patient may require extra covering. Oxygen may help if there has been prevertebral hemorrhage causing impaired heart action. Catheterization and a rectal tube may reduce intra-abdominal pressure.

Serious associated injuries must not be overlooked. With sensory pathways impaired the patient may be unaware of other injuries and be unable not only to recognize them but even to help locate them. Complete notes are made and the time of the examination put down so that any change in the findings may be related to the examination and treatment.

Lumbar puncture may be done in cases showing gross neurologic damage. Lack of the normal cardiac and respiratory oscillations and rise of pressure in the manometer on jugular pressure signify that the spinal subarachnoid space is blocked. The inflation of a blood pressure cuff wrapped about the neck and pumped to various pressures provides con-

trolled, reproducible compression that permits differentiation between a partial and a complete block.

The x-ray study is as comprehensive as the patient's positioning permits. All views are taken for stereoscopic study in the antero-posterior, lateral, and often oblique positions. X-ray studies of other parts are taken if indicated.

Injuries to the Vertebral Column

Classification.—

1. Fractures of vertebral bodies
2. Fractures of muscular processes—transverse, spinous
3. Fractures of the neural arch—pedicles, articular facets, laminae
4. Dislocations of the cervical spine
5. Fracture-dislocation without paralysis
6. Fracture or fracture-dislocation with paralysis

Fractures of Vertebral Bodies

Etiology.—These injuries constitute the largest number of spinal fractures and are usually of the compression type. The fracture may be in any vertebral body, but the majority occur at the cervicothoracic and thoracolumbar junctions. They almost always occur with the spine in flexion, as in a fall from a height. It is quite common to see more than one vertebra involved with this type of injury, and occasionally there may be several normal between two or more compressed bodies.

Diagnosis.—The patient immediately complains of pain. There is muscle spasm of the erector spinae group. Prominence of a spinous process may be noticed, and localized tenderness on palpation of the involved vertebra or vertebrae is of definite significance. The roentgenograms must be as complete as the patient's positioning permits. Stereoscopic views are often valuable, especially where the neural arch is also involved. The lateral view shows irregularity of the vertebral body with a diminution in its vertical measurement. The intervertebral disc space is usually not narrowed. Compression fractures in the thoracolumbar area show more deformity than in other areas.

One must not overlook injuries to other parts of the body when a fracture of the spine has occurred, and x-ray studies of these parts should be taken if indicated.

Prognosis.—Healing of a compression fracture of a body is good, and if the deformity has been corrected, any resulting disability can be found in the muscles and ligaments.

Treatment.—One must always rule out a fracture of the pedicle or of an articular facet, in order to exclude the possibility of a fracture with dislocation. Reduction of the fracture by hyperextension is the procedure to be employed if the body is the only element involved. The technique of reduction can be carried out by one of the following methods: Davis, Rogers, or Watson-Jones. After the fracture has been reduced, a plaster corset is applied from the suprasternal notch to the symphysis pubis (see Fig. 722). Postreduction films must show perfect reduction of the deformity. Exercises are to be carried out during the immobilization, which is usually 4-6 months, depending on the severity of the fracture. The patient is allowed up and about within a few days of immobilization.

Late cases of fracture of the body or those improperly handled may be painful. These should be treated by exercises, to develop compensatory curves above and below the old injury, or by bone graft.

A serious complication of fractures of the lumbar vertebrae is retroperitoneal hemorrhage which may cause abdominal ileus.

Fractures of Muscular Processes

Spinous Processes

These are usually caused by direct violence.

Diagnosis.—Swelling and spasm of muscles occur with local tenderness at the site of injury. X-rays confirm the diagnosis and also indicate whether any other element of the spine is involved.

Treatment.—Rest for a few days, followed by exercises, is usually sufficient. In the cervical area, due to the weight of the head, a Minerva jacket may be necessary (Fig. 723).

Transverse Processes

These occur only in the lumbar area and are caused by muscular violence.

Diagnosis.—There is severe pain, especially on lateral bending of the spine, muscle spasm of the lumbar group, and local tenderness about 3" from the midline. Anteroposterior x-rays confirm the diagnosis.

Treatment.—Plaster immobilization with the body in the neutral position is carried out for 4-6 weeks. Exercises while in plaster should be done from the beginning. Union of the fracture is a fibrous one, and therefore reduction of the fracture is not attempted. Normal activity is encouraged early.

Fractures of the Neural Arch

Pedicles

Such fractures, when they occur, are usually in conjunction with those of other elements of the spine.

there is x-ray evidence of the spinal cord being encroached upon by bone, also if there is more than one element of the spine involved by the fracture. If these findings are present, it is felt that early exploration and internal fixation are necessary.

Dislocation of the Cervical Spine

Etiology.—The mechanism of production is one of hyperflexion of the spine. The dislocation may involve one or both facets and may be accompanied by varying degrees of injury to the spinal cord.

Treatment.—Skeletal traction by Crutch field's or Barton's tongs is the method of choice and has largely displaced the manual manipulative methods. (See Chapter 11, Neurosurgery.) The tongs are placed below

Fig 722—Postural reduction by hyperextension for compression fracture of the vertebral bodies

Articular Facets

These are usually involved in cases of fracture-dislocation. It is necessary to have x-rays taken in various projections to demonstrate these features.

Laminae

Direct violence is usually the cause of these fractures and the fragments may cause direct pressure on the spinal cord.

Treatment

One must consider whether there is a partial or complete subarachnoid block or whether

the parietal eminences and project into the outer table 3 mm. Following reduction, a Minerva jacket is applied with the head in moderate hyperextension. The jacket is worn for 2 months, after which a plaster or felt collar will give sufficient hyperextension for an additional month. X-rays must be repeated to see that the reduction is being maintained, and if it is not, a fusion operation will be necessary.

Fracture-Dislocation of the Spinal Column Without Neurologic Involvement

Etiology.—These injuries are usually caused by severe flexion or extension of the spine. The commonest findings are a compression fracture of a vertebral body with a fracture of one or both articular facets and a dislocation forward of the involved body upon the ones above and below. The pedicles, laminae, and spinous processes may be included in the fracture.

Nonsurgical Treatment.—For the cervical fracture-dislocations, skeletal traction applied

with the Crutchfield or Barton-Cone skull tongs is the best method. Halter traction is satisfactory only in the emergency management. Repeated x-rays are essential to follow the course of reduction. Manometric studies are to be carried out to see whether the traction is satisfactory when a subarachnoid block has been present.

For the thoracic and lumbar fracture-dislocations, traction on the shoulders and lower extremities can be tried with special apparatus. Manometric study should be repeated if a block has been previously demonstrated.

Surgical Treatment.—Exploration is indicated when spinal block is partial or complete. When the fracture involves more than one element of a vertebra, stabilization is required.

Exploration is carried out as soon as the condition of the patient permits. Traction is applied when the involved area has been exposed and the spinal cord is under direct inspection. When restoration of the vertebral canal is accomplished, internal fixation is secured by means of bone grafts.

Postoperative management is simplified due to the operation. A Minerva plaster jacket is used for cervical cases and bivalved casts for injuries lower in the spine.

When bladder control is lost, Munro's tidal irrigation is started at once. If urinary infection cannot be controlled by drainage, suprapubic cystostomy may be necessary.

Pressure sores can best be prevented by frequent turning; this is much safer after internal fixation of the spine.

Fig 723.—Minerva or cervicothoracic jacket. This cast includes the head, neck, and thorax, leaving the face, chin, and shoulders free for movement.

STATIC DISORDERS OF THE VERTEBRAL COLUMN

ALBERT A. BUTLER, M.D.

FIBROSITIS

Fibrositis, fibromyositis, and muscular rheumatism are terms used for pain in the soft tissues, characterized by muscle spasm and tenderness localized at "trigger points" or sites of maximum tenderness from which pain seems to be referred. Commonly there are associated tender nodules in muscle or subcutaneous tissues, which are called "fibrositic nodules."

Etiology.—The cause is unknown, lowered general resistance, exposure to cold, dampness or trauma, fatigue, mental anxiety, metabolic toxins, intestinal intoxication, bacterial toxins, gout, excessive exercise, faulty posture, endocrine disease, muscular disturbances, and so on are variously considered the cause. If we consider it a symptom complex rather than a clinical entity, we have a useful term which does not exclude a more accurate diagnosis if it can be established.

Pathology.—Sections of affected tissues show pathologic changes of a rather inconsistent nature. Inflammation of interstitial connective tissue of affected muscle, nodular in distribution, is described and is presumed to cause a spastic reaction in surrounding contractile tissue which becomes palpable. The subcutaneous nodules on biopsy appear to show fat herniation through a fibrous capsule, which on cross section is edematous and hemorrhagic.

Clinical Features.—The pain may be acute or insidious in onset. Muscular spasm is usually an outstanding feature. Certain "pain patterns" are recognized, such as *torticollis*, affecting sternomastoid, trapezius, and cervical muscles; *lumbago*, affecting lumbar and gluteal muscles, and so on. Posture is altered and movements are limited due to the muscle spasm. Passive movements are usually much freer than active ones if carried out slowly; if abrupt, they may precipitate an acute exacerbation. There may be reflex or sensory changes, and straining usually aggravates the pain.

Differential Diagnosis.—The determination of the source of pain is notoriously difficult. We must recognize that the same false localization and reflex muscular effects may occur from involvement of deep parietal structures and certain viscera. Fibrositis of the middle part of the left trapezius may produce an angular type of pain by virtue of T2, 3, 4 reflex. Involvement of cervical muscles commonly produces headaches. Fibrositis of dorsolumbar muscles may mimic appendiceal or ovarian pain, T9-12. Scalenus anticus involvement may resemble gall bladder disease, and C3, 4, 5 reflex via the phrenic nerve. Psoas fibrositis may resemble abdominal, genitourinary, or vertebral lesions.

These false localizations can be reproduced by the injection of irritating solutions at various levels into paravertebral tissues. At L1, for instance, pain will radiate to loin, inguinal, and scrotal regions, with rigidity and deep tenderness in lower abdominal wall, resembling renal colic.

Ischemia is an important factor in producing pain, and there is a great difference in the action to exercise, e.g., the intermittent indication of Buerger's disease and the pain cardiac ischemia. If a tourniquet is used

to produce ischemia in a limb, there is much less pain at rest than with exercise, presumably due to a difference in the chemical changes in the tissues.

Investigation, to be adequate, must exclude visceral, neurologic, and skeletal disorders.

Treatment.—Heat, massage, analgesics, and local injections of Novocain are often successful in clearing up acute attacks. An exercise program and attention to general health are designed to prevent recurrences.

OSTEOARTHRITIS OF THE SPINE

Osteoarthritis of the vertebral column is generally taken to include traumatic and degenerative changes in the intervertebral and apophyseal joints. The two main types are hypertrophic spondylitis and spondyloarthritis.

Hypertrophic Spondylitis

This refers to changes in the intervertebral joints which are symphyses, and so the pathologic changes differ from those seen in diarthrodial joints. Synonyms are *spinal osteophytosis* and *degenerative disc disease*. The latter stresses one factor in a process which affects all the tissues of the joint. There is loss of the turgescence of the intervertebral disc, both with age and with degenerative processes. This dehydration of the disc is an important factor in its narrowing. As a result, there is interference with its function as a cushion between the vertebral bodies. Trauma to the adjacent bone then gives rise to peripheral ossification. This affects the bulging outer fibers of the annulus fibrosus. It probably lifts the periosteum at the attachment of these fibers and produces the hypertrophic reaction. The process is more marked anterolaterally than it is in the region of the anterior spinal ligament, presumably due to the protection that the ligament offers to the disc. The changes are absent or less marked posteriorly, because it is produced by a flexion mechanism. There is an associated reduction of spinal movement, and abnormal strains are thrown on the apophyseal joints; this may produce secondary degenerative changes there. Calcification of degenerated discs is occasionally seen.

Clinical Features.—Hypertrophic spondylitis is occasionally present to a very marked degree and entirely symptomless. Examination will show, however, that there is a good deal of limitation of spinal movement. Very often there is a complaint of pain, which is aching in character. Following strenuous exercise, or with the onset of fatigue, symptoms become more severe. If patients maintain one position for a prolonged period of time, it is difficult to start moving. After a short period of limbering up, there is a good deal of improvement. X-rays show marked beaking of the vertebral bodies with narrowing of the intervertebral space. This condition may be associated with a posterior protrusion of the nucleus pulposus, in which case that complica-

the cervical region placed lateral to the discs. Involvement of these joints is identical with that seen in other diarthrodial joints in the body. (See Chapter 37, Joints.) Histologically this is a true osteoarthritis: Degeneration of articular cartilage due to injury, rapid erosion due to overuse, slow erosion with the years, or vascular and metabolic disturbances predispose to or accelerate the process. The changes in the hyaline cartilage of the joint are quite marked before erosion to bone results. When there is bony contact, marked hypertrophic changes occur with the production of peripheral chondro-osteophytes. As one would expect from the pathologic changes, symptoms are present long before there is x-ray evidence of hypertrophic change.

Fig 724—Hypertrophic spondylitis

tion would predominate and require whatever treatment was necessary on its own merits. There may also be associated changes in the apophyseal joints. These would then probably account for the predominant symptoms.

Hypertrophic Spondyloarthritis

This is an involvement of the synovial joints of the vertebral column, which are mainly the apophyseal joints, but there are also the tiny intervertebral synovial joints in

Clinical Features.—Pain and stiffness are often severe and characteristically influenced by the weather. In fact, in many patients their joints act as an excellent barometer. A fall in pressure is associated with an exacerbation of their symptoms. Symptoms are worse in the morning but soon improve as the patients start moving about. They often discover for themselves that setting-up exercises before getting out of bed are beneficial. Symptoms are relieved by gentle exercise and aggravated by strenuous activities. The regions involved are

proportional to the sites of maximal strain. These occur most frequently at the apex of the normal curves. Lumbosacral and lumbar regions account for two thirds of the involvement; most of the others occur in the cervical region. Acute exacerbations of symptoms may produce marked muscle spasm. Reflex referral of pain occurs according to the innervation of the part concerned. Novocain infiltration may be used to relieve muscle spasm or as a paraspinal block for both diagnostic and therapeutic purposes.

Fig. 725.—Hypertrophic spondyloarthritis

Treatment.—

General Measures

1 Dietary directions may be necessary to deal with nutritional deficiency or alterations from the normal weight.

2. A regular exercise regime and regular hours of sleep should be established.

3 Mental attitude should be improved by the avoidance of worry and fatigue. The co-operation of family and associates is necessary to create a cheerful atmosphere.

4 Supplementary vitamin or hormone therapy is occasionally indicated.

5. Analgesics and sedatives are used as temporary expedients for rest and relief of pain.

Local Measures.—

1. Postural defects are corrected by instruction in remedial exercises.

2 Heat and massage are used for their soothing and palliative effects during an acute exacerbation.

3 Body casts may be used for a short period to give support while building up musculature.

4 A Harris lumbosacral brace may be used to limit painful movement.

5. Manipulation is often dramatic in giving temporary relief. Instability or nerve root involvement must be positively excluded. The principle is to place the involved joints in the positions of the extremes of their movement and then to stretch them slightly. The mechanism of relief is the snapping of light capsular adhesions.

6 Operative measures are worth while for severe and well-localized lesions. Occasionally an arthrectomy suffices and has the advantage of early mobilization. The vast majority, however, that come to operation require spinal fusion.

7. X-ray therapy is of doubtful value, but usually some temporary relief of pain is achieved.

ANKYLOSING SPONDYLITIS

This condition is characterized by obliteration of the sacroiliac joints, ankylosis of the apophyseal joints, calcification of spinal ligaments, and periphery of the intervertebral joints. It is often associated with involvement of peripheral joints. There are many synonyms. *Marie-Strümpell spondylitis* and *rhumatoid arthritis* of the spine being used fairly commonly. Others, such as *spondyloarthritis ankylopoietica* and *spondyloire rhizomelique*, are occasionally used. The disease follows a fairly characteristic pattern. Ninety per cent of cases occur between the ages 15-35 years, and they

are nearly all males. It is sometimes seen in children, in association with Still's disease, which is childhood rheumatoid arthritis. It occurs in older persons as an exacerbation of the disease acquired during the usual age period. The cause of the disease is unknown. It is presumed to be an inflammatory process, as some focus of infection, recent or remote, can usually be established. There is probably an important allergic factor.

Clinical Features.—The onset is slow and characterized by pain and stiffness. There may be reflex referred pain simulating other conditions. Once started, the disease appears to be progressive, but the rate is variable, anywhere from 2-15 years, before it goes on to spontaneous remission. During this time there may

and the apophyseal joints. This is followed by involvement of the sacroiliac joint which is the first one recognizable radiologically. This is followed by calcification in the spinal ligaments and the outer layers of the annulus fibrosus. When the process is advanced the x-ray acquires the "bamboo spine" appearance. About half the cases show peripheral joint involvement to some extent. It is unusual to have involvement of the small joints of the hands and feet. In fact, the hips and knees are most commonly associated in the involvement. Histologically the process appears rheumatoid in nature. This does not explain the age and sex incidence, the response to treatment, the rarity of subcutaneous nodules, or the early calcification of periarthritic tissues. Acute cases,

Fig 726 —Taylor brace shown in posterior, lateral, and anterior views. Useful for cases requiring support for lower dorsal, lumbar, and lumbosacral disorders

be periods of acute exacerbation. The blood sedimentation rate is always high. Limitation of chest expansion and characteristic limitation of spinal movement are early features and may enable one to establish the diagnosis clinically before x-ray changes can be detected. The sacro-iliac joint is involved in 90% of cases. It is spared only when the disease is restricted to the upper vertebral regions. It would appear clinically that the small joints of the spine are first involved, namely, the *costovertebral*

accompanied by fever, inanition, and gross muscle wasting, may threaten life, but these are fortunately rare.

Treatment.—The general measures described for osteoarthritis of the spine are also applicable. X-ray therapy is of much greater value, and in the majority of cases it completely arrests the disease. It produces an apparent improvement due to the abolition of pain and muscle spasm. Two or three courses of therapy are necessary, at about three

Fig. 727 —Marie-Strümpell spondylitis (See opposite page for complete legend)

monthly intervals, in order to consolidate the cure. Corticosteroids have a limited use in the early cases. Occasionally in neglected cases or if the deformity appears progressive, a Taylor brace may be of value. Commonly, with adequate treatment, it is unnecessary, and if the disease is very active it is not well tolerated. A plaster bed with corrective felt pads may also be useful in the few cases in which the patients

do not respond readily to x-ray therapy. Surgery is necessary in neglected and late cases to correct deformity by osteotomy or by arthroplasty. The latter is most often indicated in the hip joint.

COCYDYNIA

Coccydynia refers to pain in and around the coccyx and is therefore just a symptom

D.

F, Irregularly distributed calcification of the anterior longitudinal ligament.
 The explanation of the rigid poker spine is apparent from these x rays

complex. It is often associated with trauma. There may be a fracture or there may be traumatic arthritis in the sacrococcygeal joint. Congenital variations in the structure of the coccyx may resemble an old fracture. Pain may be due to a soft tissue inflammatory process, either traumatic or infective in origin. The condition is commoner in females than in males. In some there are no localizing signs, and the painful coccyx is presumably psychosomatic in origin. If there is displacement of the coccyx, it may be palpated externally or by rectal examination or demonstrated in x-ray. Sacrococcygeal arthritis shows well-localized tenderness and aggravation of pain by movement of the joint. Pain with walking and exercise may indicate that the trouble lies in the soft tissue attachments of the coccyx.

Treatment.—

1 Protection from pressure may be obtained by using an air cushion or by sitting up straight on a hard chair. The weight is then taken on the ischium and the coccyx is relieved of any local pressure.

2 Short-wave diathermy and massage are occasionally beneficial.

3 Novocain infiltrations into the site of maximum tenderness are worth a trial.

4 In selected cases with a clear-cut abnormality and failure of conservative treatment, excision of the coccyx may help. It is important to avoid operation in a neurotic patient.

ADOLESCENT KYPHOSIS

This is a chronic disease producing a dorsal or dorsolumbar smooth kyphosis, commencing between the ages of 12-16 years. It may be symptomless or it may cause pain and fatigue. Occasionally the pain and stiffness are quite severe. The synonyms are *Scheuermann's disease*, *vertebral epiphysitis*, and *osteochondritis*. X-ray shows wedging of the vertebral bodies with quite a marked, smooth kyphosis. There appears to be fragmentation of the ring epiphysis and later on development of anterior marginal osteophytes. It has been thought that these changes are due to a vertebral epiphysitis and osteochondritis. It is now, however, believed that it is entirely secondary to changes in the intervertebral disc. Schmorl demonstrated

prolapse of the nucleus pulposus into the spongiosa of vertebral bodies in all his specimens of adolescent kyphotic spines, which came to dissection. This would result in loss of movement and tilting of the vertebrae. It is believed therefore that there are Schmorl's nodes at every level in the affected region. They are only seen in the x-ray if there is a reactive condensation of bone around the prolapse. This disorder is usually associated with shortened hamstring muscles.

Fig. 728—Adolescent kyphosis

Treatment.—

1. Mild cases are treated by head traction, using a head halter with 20 pounds for 20 minutes daily.

2. Intermediate cases may also require the use of a Taylor brace between exercise periods.

3. Severe cases may require recumbency for several months in a plaster bed, with gradual correction by felt pads, along with hourly hyperextension exercises. All patients probably benefit from using a plaster bed at night.

SENILE KYPHOSIS

Senile kyphosis is probably due to degenerative changes in the intervertebral disc. There may be associated nuclear protrusion or annulus bulging, but these would not be etiologic factors. There is a smooth upper and mid-dorsal kyphosis with narrowing of the intervertebral discs and a forward tilt of the vertebrae. The discs are thin and show loss of elasticity. There may be associated degenerative

as anterior fusion occurs. There may be a lot of distress in the intervening period. The remainder of the spine may be stiff. If compensatory curves cannot develop, the patient remains markedly stooped.

Treatment.—Heat, massage, and analgesics give symptomatic relief. Postural exercises are usually helpful. A Taylor brace in the day and a plaster bed at night are sometimes useful.

SENILE OSTEOPOROSIS

Senile, idiopathic, or postmenopausal osteoporosis is characterized by backache and increasing deformity as vertebrae collapse. It affects middle- or old-age persons. The decalcification is not necessarily generalized. Often the vertebral collapse occurs in several regions. The x-ray shows lozenge-shaped intervertebral discs due to the turgescence of the disc causing a smooth bulge into the soft spongiosa. It is apparently a disturbance of bone metabolism.

Clinical Features.—There are loss of movement and moderate backache during quiescent periods. Vertebral collapse causes acute exacerbations. If there is root involvement, pain may be intractable. Every movement causes severe muscle spasm and radiating nerve pain.

Treatment.—

1. Chronic cases are treated by hyperextension exercises, plus a plaster bed at night and a brace in the day.

2. Acute cases are treated by bed rest, with immobilization if necessary to relieve symptoms. Chordotomy for intractable pain may be considered.

3. High protein diet, vitamins, calcium, strontium, stilbestrol, and testosterone seem to help recalcification, but it is a slow process. Symptoms are relieved long before there is radiologic evidence of recalcification.

VERTEBRAL OSTEONCHONDRITIS

Vertebral osteonchondritis (Calvé's disease) is an avascular necrosis in the vertebra. Presumably this is due to an infarct, but histologic studies have not been made. It is in the same group of disorders as Kienbock's disease in the semilunar, Kohler's disease in the tarsal scaphoid, etc. It affects only one vertebra, usu-

Fig 729 —Senile kyphosis

calification in some of them. Some of the vertebrae are in contact anteriorly and show fusion of the spongiosa across the intervertebral disc. Senile degeneration alone would not account for the condition. There is probably an added postural defect or occupational stress. The texture of the bone is normal unless there is an associated defect.

Clinical Features.—Pain may be local or radiating in character and is often worse when lying down. It is self-limiting, disappearing

Fig 730 —Senile osteoporosis

Fig 731 --Vertebral osteochondritis before and after treatment

ally lumbar or lower dorsal, in the 5- to 10-year age group. It is accompanied by kyphosis, pain, fatigue, tenderness, and muscular rigidity. The x-ray resembles Pott's disease of the rarer central body type. There is fragmentation with collapse of the vertebral body, but the appendages remain normal. There is tilting of the adjacent vertebrae, producing a sharp kyphosis, with the affected vertebral spinous process at the apex. The vertebral body may reduce to a wafer of bone, but with adequate treatment it becomes reconstituted to appear normal. It is distinguished from Pott's disease by the following:

- 1 Intervertebral disc space normal
- 2 No paraspinal abscess
- 3 Absence of systemic reaction
4. Negative tuberculin test

Treatment.—Bed rest in a hyperextension frame with four-point thoracic and pelvic traction, or a plaster bed with felt pads, is used till there is relief of pain and muscle spasm. A Castex corset, or spinal brace, is used until there is x-ray evidence of reconstruction of the affected vertebra.

SCOLIOSIS

Structural scoliosis is a condition in which there is a lateral curvature of the spine, associated with altered shape and rotation of the vertebrae. It is important to separate the so-called *functional scoliosis*, which is really only a postural defect, and the *simple unprogressive structural* cases, which are not significant, from the *progressive structural* ones, which if untreated go on to a horrible deformity.

Early recognition and careful follow-up is the only way to select intelligently the few cases that require radical treatment. A glance at the flexed spine in all routine examinations at school age is imperative and discloses even mild curves which should be noted and reviewed in 3 months. If there is any progression, a scoliosis record must be made. It is important to realize that there is, as yet, no substitute for continuous observation throughout the growth period. A curve may appear unprogressive during a period of slow spinal growth and then may progress rapidly and suddenly during a phase of rapid growth.

Steindler refers to three periods of rapid growth:

- 1 Birth to 2 years
- 2 5 to 10 years
- 3 Puberty to cessation

Closer observation is necessary at these times. When growth is complete, there is not likely to be any substantial change in the condition. In view of the fact that longitudinal growth of the vertebrae is by enchondral ossification, it is difficult to be sure just when it ceases. Risser has observed that ossification of the iliac apophysis is an accurate index. It ossifies anteriorly to posteriorly, and as it curves around the posterior superior spine to point toward the sacroiliac joint, vertebral ossification is complete. This varies between 12-19 years, and indicates the preferable time for spinal fusion if that is necessary.

Method of Recording.—If the periodic observations are reduced to a simple formula, it leads to more accurate records and is more easily understood if there are different observers. The x-rays should include anteroposterior views in the standing, sitting, and supine positions, extending from the iliac crests to occiput, each on one long film. A clinical photograph with the bony landmarks outlined is also taken. The *curves* are named according to the region and the side of their convexity. The apex and the limits of the curve are noted. The curve is measured by an empirical method, the last intervertebral surfaces still pointing into the concavity form the base line, and perpendiculars are drawn from these. The angle toward the axis of the spine is then measured.

Wedging is noted on a scale of 1 to 4 plus, measurements being made on the vertebra showing maximal wedging, and this is usually at the apex of the curve.

- $$\begin{aligned} 0 \text{ to } \frac{1}{6} &= + \\ \frac{1}{6} \text{ to } \frac{1}{3} &= ++ \\ \frac{1}{3} \text{ to } \frac{1}{2} &= +++ \\ \text{More than } \frac{1}{2} &= ++++ \end{aligned}$$

Rotation of the vertebrae is also recorded where maximal, usually at the apex. It is positive if to the side of the concavity and negative if to the side of the convexity. It is measured by the relationship of the tip of the spinous process to the edge of the vertebral body.

Fig 732—A, Right thoracolumbar scoliosis showing measurement of primary and secondary curves (idiopathic type)

B, The photographs show the marked thoracic cage deformity, kyphosis, and lordosis which accompany the rotational elements of a severe scoliosis

C, Correction obtained by an operation to mobilize the primary curve and turnbuckling a hinged cast.

D, The correction is maintained by bone grafts as illustrated

To concavity	To convexity
0 to $\frac{1}{3}$ = (+)	(-)
$\frac{1}{3}$ to $\frac{2}{3}$ = (++)	(--)
$\frac{2}{3}$ to edge = (+++)	(---)
Beyond edge body = (++++)	(----)

Usually there are three curves—the middle one being primary and the other two secondary. They are compensated when the sum of the curves to opposite sides is equal. The primary curve shows the most structural change and is the larger curve. Double primary curves are seen occasionally, being equal in all respects.

With high curves, *bending films* are necessary to determine the mobility of the curves. With lumbar scoliosis, this is done by the *pelvic tilt test*, the film being taken with a 3" lift under one buttock and then the other. If there is residual angulation in the compensatory curves, the total determines the limit of desirable correction in the primary curve. It is important to avoid overcorrection. Partial correction may be of remarkable value, if it restores compensation of the residual curves.

Types of Scoliosis.—

Functional scoliosis is a postural defect which can be voluntarily corrected (See postural defects.) Adaptive changes in the structure of vertebrae are absent or minimal. This differs from scoliosis due to a short leg or to other deformities of the lower extremities. If the postural defect or the deformity of the lower extremities is corrected, the scoliosis is no problem.

Structural scoliosis is due to an intrinsic defect in bone, nerve, or muscle. It cannot be voluntarily maintained in a corrected position.

Classification according to etiology is customary and the approximate incidence is noted.

- 1 *Muscle* (a) Idiopathic—80%
(b) Thoracogenic—2%
- 2 *Bone* (a) Congenital anomalies—3%
(b) Osteochondrodystrophy (Morgagnoli's disease)—1%
- 3 *Nerve* (a) Poliomyelitis—10%
(b) Neurofibromatosis—2%
(c) Friedreich's ataxia—1%
(d) Spastics—1%

Clinical Features.—Very often scoliosis is unrecognized until someone remarks that there is a prominent hip or a high shoulder, or per-

haps it is picked up in a school medical examination. Commonly it gives no symptoms in youth. So long as mobility and good muscular strength are present, compensation for the deformity appears adequate. Later there is likely to be degenerative change in the joints at the sites of maximal curvature. In very severe deformity, cord involvement with paraplegia can occur. With extreme curves there is secondary visceral embarrassment, which shortens life. This is statistically evident in curves over 50 degrees, is proportional to the severity of the curve, and is most harmful in the thoracic region. It is therefore imperative that the condition be treated before irreversible changes occur, with such dire consequences.

Fig. 733.—The author's distraction brace.

Treatment.—

Palliative.—Exercises improve the sense of well-being and compensate for the ill effects of the curvature, but they do not appreciably or permanently alter the curve.

Corrective.—

1. *Rest in recumbency* will produce appreciable correction. Albee used a Bradford frame

with three canvas bands to give a cross pull against the curvature.

2. A *distraction brace* gives traction on the spine between the pelvis and the occiput. It is limited by the pressure that can be tolerated on the chin and occiput but is effective in very young children. The Milwaukee brace uses fixed distraction; the Butler brace uses four elastic distraction units attached by ball-and-

socket joints to the headpiece, allowing some spinal movement.

3. *Reverse curve plaster jacket* is used on the principle that pressure against the curve may alter growth by compression. It does not appear to do this to an appreciable extent.

4. *Plaster casts* applied in corrective positions with and without crutch supports are of doubtful value. Often there is marked progres-

sion of the curvature in spite of such appliances.

Operative Treatment—It is generally recognized that a mature spinal fusion is the only means of maintaining a correction of structural scoliosis.

Opinions differ widely, but following are Cobb's indications for spinal fusion:

1. A severe scoliosis usually over 50 degrees and correctable at least 20 degrees, in patients preferably 12-21 years of age
2. A lesser curvature which is increasing under conservative management and will become severe.
3. Unstable scoliosis, preferably in patients 13-14 years of age
4. Pain which can be relieved by fusion, this is usually in the older patient

In some cases one is forced to fuse at an early age, in which case a short fusion is done as a compromise, and it is extended after vertebral growth ceases. This is more likely to be necessary in paralytic curves and in some congenital ones with multiple anomalies.

There is a variety of methods used for correction of the curvature prior to spinal fusion:

1. **Risser Jacket**—A corrective cast is applied by
 - (a) Head traction
 - (b) Albee-Compere derotation table
 - (c) Other methods

Hinges are incorporated back and front over the apex of the curve. Turnbuckles are attached and correction carried out as tolerated. When the desired position is obtained, the cast is reinforced and a large window is cut out over the spine for the fusion. This is preferred for high and rigid curves.

2. **Transsection Jacket**—In dealing with double primary curves or mobile curves, the cast may be immediately sectioned and placed in maximal correction. The cast is reinforced in this position, the window cut, and operation proceeded with.

3. **LeMesurier Hammock**.—This is an ingenious method using a fish-net hammock. The patient is suspended by overhead pulleys in the hammock, with suspension from the

upper arm and leg as well, giving a four-point suspension. When the correction is considered adequate, a padded cast is applied. The posterior window can then be cut and operation proceeded with.

The corrective jackets are usually retained for 6 months and some protection used for a further 6 months.

INFECTIOUS DISORDERS OF THE VERTEBRAL COLUMN

More than half of all bone and joint tuberculosis occurs in the vertebral column. By contrast, pyogenic infections of the spine are extremely rare, accounting for a very small proportion of all the cases of pyogenic osteomyelitis. Brucellosis, actinomycosis, typhoid

Fig 733—Tuberculosis of T2-3 with collapse.

spine, and gonococcal and syphilitic arthritis are all rarities

Tuberculosis of the Spine

Pott's disease may occur at any age, but it is most common in the young. The involvement of the spine is secondary to tuberculosis elsewhere in the body, usually a tuberculous lymphadenopathy. Minor trauma, or a localized degenerative change due to the systemic toxemia, predisposes to an endarteritis, giving rise to the initial focus. In the spine, this commonly

2. It may follow the course of muscles, nerves, and blood vessels, to reach long distances.

3. It rarely extends into the vertebral canal, giving rise to paralysis.

The cold abscess at a distance from the diseased area is found in about 20% of cases. It may account for a swelling anywhere between the occiput and the heel, but the following are the commoner types:

1. *Retropharyngeal abscess*, arising in a cervical vertebra, perforating the prevertebral

Fig. 736.—Plaster bed for treatment of tuberculosis

occurs in the vertebral body beneath the hyaline cartilage. This epiphyseal involvement accounts for two thirds of the cases. The periosteum, central vertebral body, and appendages are involved with descending frequency. Subsequent events depend on virulence, resistance, localization, complications, and treatment. Caseation in the vertebral body permits collapse and expression of tuberculous debris, forming a cold abscess.

1. This may form a paraspinal abscess

fascia, and pointing at the edge of the sternomastoid muscle.

2. *Intercostal abscess*, originating in a thoracic vertebra and following nerves or vessels.

3. *Psoas abscess*, from a lumbar vertebra, passing along the iliopsoas to the inguinal ligament on either side of the femoral artery.

Clinical Features.—The onset of the disease is often insidious, particularly in children who appear just out of sorts. The presence of a swelling, which investigation shows to be a

cold abscess, or even the development of a sharp kyphosis may be the first incidents that lead the individual to seek advice. Occasionally low back pain, with acute sciatic radiation, occurs and closely simulates the symptoms of a prolapsed intervertebral disc. Inquiry elicits the symptoms of systemic involvement, loss of stamina, malaise, loss of weight, and possibly night sweats. Localization may be indicated by a tired ache or tenderness, or the pattern of referred pain may indicate the nerve root involvement. Kyphosis, localized rigidity, tenderness, or hyperesthesia may be noted. The x-ray in advanced cases shows collapse of the affected vertebral bodies and a paraspinal abscess. With early involvement, the loss of intervertebral space may be difficult to interpret, but this is soon followed by decalcification, with a blurring of bony trabeculation. The hemogram may show increased sedimentation rate, lymphocytosis, and leukopenia. Muscle spasm is always present, and there is painful limitation of spinal movement. A young child will pick up an object by crouching on the hands and knees instead of bending the back. Paraplegia is a serious complication which is not uncommon when the disease is in the dorsal region.

Treatment.—It is essential that treatment be correlated with an understanding of the disease in all its phases.

1 *Systemic treatment* by bed rest, controlled exposure to sun and wind, and intelligent diet is as fundamental as adequate immobilization of the diseased area. Mental health is achieved by education, occupational therapy, and an interesting environment, with positive training in the philosophy of contentment. Supportive therapy, iron, vitamins, blood transfusions, etc., and antibiotics are used as required. The response to this regime is more effective in children than in adults, and therefore surgery as an aid to recovery is used accordingly.

2 *Streptomycin and other antituberculosis drugs* systemically and locally in wounds and sinuses have improved the scope of surgery in Pott's disease.

3. *Arthrodesis* of the affected region achieves a more effective local immobilization than external means but does not in itself cure the disease. Delay for several months is

essential in early disease to determine the number of vertebrae involved. Multiple involvement is a distinct possibility. Fusion is a delayed aid to recovery, only becoming effective when union is sound. One must be sure that the response to the general regime will be adequate for several months to make the procedure worth while. Operation, when performed too early, increases the mortality rate; if too late, just prolongs the illness! Bradford frames or similar orthopedic appliances are commonly used to maintain the child in the position of hyperextension. Plaster beds with

Fig 737—Museum specimen showing tuberculosis of lumbar spine

turning shells are adaptable to any age or condition. There are many methods of spinal fusion based on the original Albee and Hibbs procedures. The most popular are twin tibial grafts and "H" shaped iliac grafts. When the systemic disease is arrested and the vertebral lesion is recalcified, graduated convalescence

is permitted. This consists of recumbency without plaster, increased exercises, sitting up in bed, and so on, to a gradual resumption of full activity over several months. Close supervision is required to guard against a possible relapse.

Excision of the Nidus of Infection.—Extirpation of an abscess with bony and cartilaginous sequestra is performed when simpler measures fail or when, due to great size, chronicity, or mixed infection, a conservative approach is likely to lead to failure.

Diodrast may be used to outline the size and contour of the abscess cavity. Tryptic enzymes such as Varidase have been used to remove inspissated exudate from a draining sinus prior to this examination. It is used, but in smaller dosage, when there is a closed abscess, because of the severe reactions it may produce. When the abscess wall is totally excised, the vertebrae and discs are then exposed, and carious material can be removed. Cancellous bone chips and streptomycin may then be inserted as an aid to anterior fusion.

Antibiotics and antituberculosis drugs are efficient protection against dissemination of the disease by the operative procedure. Permanent healing is less likely with incision and drainage because of constriction within the tract and irregular pouching, preventing free drainage. There may also be retained sequestra at the primary focus or along the sinus.

Sacroiliac Tuberculosis

Tuberculosis of the sacroiliac joints is not uncommon. It is chiefly seen in young adults and is serious if associated with multiple lesions elsewhere in the body. Multiple sinus formation is also an unfortunate characteristic in this region.

Clinical Features.—The diagnosis is usually missed until a painful limp develops. Pain may be localized to the sacroiliac region, but very often it is a diffuse low back pain. Occasionally it may be referred into the gluteal region and posterior aspect of the spine. A sciatic type of scoliosis is often seen. Either this or the muscle spasm in the gluteal region accounts for the limp. Abscesses are commonly seen and may present anywhere around the pelvis, most frequently pointing posteriorly

over the joint. The usual systemic manifestations of the disease are present. X-rays show erosion of the joint surface and a zone of decalcification around this, but in the early stages it is difficult to detect any change.

Treatment.—Systemic treatment is the same as for tuberculosis elsewhere in the body. A sacroiliac joint is immobilized by the use of a plaster spica. If there are sinuses, a plaster bed is used. Streptomycin locally as well as systemically is very effective in obtaining healing of the sinuses and quiescence of the disease. This is followed by arthrodesis of the joint by one of the extra-articular methods.

Osteomyelitis of the Spine

Pyogenic infections of the vertebrae are most commonly due to *Staphylococcus aureus*. It is usually a blood-borne infection, rarely a complication of lumbar puncture, spinal operation, or injury. It may occur as a complication of septicemia in children, or it may localize in the vertebral body or the appendages of the vertebra as the result of a bacteremia. *Acute cases*, usually in the appendages, are characterized by fever, local tenderness, muscular spasm, and swelling of the overlying soft tissues. Oblique x-rays may show involvement of the interarticular joints. The *chronic type* is more often in the vertebral body, is slow in onset, and resembles tuberculosis. Blood culture, hemogram, and tuberculin test often help to establish the diagnosis. The x-ray changes are late, they first show narrowing of the intervertebral space and then collapse of the vertebral body. Subsequent sequestration and resorptive changes in the bone, with thickening and bridging of the vertebrae, become characteristic. The complication of mediastinal abscess, empyema, suppurative pericarditis, or extradural abscess may be serious.

Treatment.—Antibiotics are used in large dosage, combined with general supportive measures such as blood transfusions and parenteral fluids. The spine is protected in a plaster cast or plaster bed. Abscesses may have to be drained, and if there is sequestration in an inaccessible location, drainage may persist. The hypertrophic reaction to the disease usually makes spinal fusion unnecessary, although it has been used in some of the chronic cases to give local support.

Gonorrheal Spine

Gonorrheal arthritis is not uncommon, but its occurrence in the spine is rare. It is suspected when there is pain and rigidity of the vertebral column following a neisserian urethritis. The likelihood is increased if other joints are involved and if the complement fixation test is positive. It may produce a marked ankylosis.

Treatment.—The nidus of infection in the genitourinary tract must be eliminated first. Antibiotics, particularly penicillin, and the sulfonamides are of inestimable value. Local treatment of the spinal lesion may be symptomatic, with bed rest, followed by a plaster corset, until completely cleared.

Syphilitic Spine

(See Fig. 562)

Syphilis is becoming a rare disease, and syphilitic involvement of the vertebral column is a great rarity. There is a variety of possible lesions:

1. Localized periostitis
2. Congenital syphilitic epiphysitis
3. Syphilitic osteochondritis
4. Gummatous lesions
5. Extension from a syphilitic ulcer
6. Neurotrophic changes producing a Charcot spine

Cervical involvement is most likely by extension from a syphilitic pharynx. It is said to simulate Pott's disease. Other stigmas of syphilitic infection—Hutchinson teeth, nasal catarrh, suppurative otitis, interstitial keratitis, blood Wassermann, and x-ray appearance—help to establish the diagnosis.

Treatment.—The systemic disease is treated by penicillin and other antisyphilitic drugs as indicated. The local condition may require mechanical support. If there is instability, as with a Charcot spine, spinal fusion is indicated.

Other Infections of the Spine

1. *Typhoid fever* sometimes produces a periostitis and osteitis of the spine
2. *Undulant fever* may produce abscesses in the vertebral body and intervertebral disc, or

a hypertrophic periostitis. The general symptoms of the disease, plus *Brucella agglutination*, low white count, fever, and high sedimentation rate, aid diagnosis.

3. *Actinomycosis* of the spine shows extensive bone destruction and numerous draining sinuses. Biopsy of the granulation tissue, with discovery of the ray fungus, establishes the diagnosis. Treatment is with penicillin, sulfonamides, usually combined with surgical drainage and mechanical support of the spine. Occasionally iodides and/or x-ray therapy are beneficial.

4. *Blastomycosis* resembles Pott's disease; the diagnosis is established by biopsy and microscopic findings. The prognosis is poor.

5. *Echinococcus cysts* of the spine require resection of the part, followed by mechanical support.

Fig. 738—Metastatic carcinoma of L2 with collapse

NEOPLASTIC DISORDERS OF THE VERTEBRAL COLUMN

Tumors of the vertebral column are rather rare. Those that do occur are mostly malignant and usually metastatic. Metastases occur from the prostate, breast, kidney, gastrointestinal tract, female genital organs, thyroid, and lung, in descending order. The preponderant opinion is that the tumors are blood-borne, the malignant emboli lodging in marrow capillaries.

Primary Benign Tumors

1. Osteomas.
2. Osteochondromas—these are usually symptomless and no treatment is required.
3. Chordomas—the remnants of the embryonic notochord.
4. Hemangiomas—usually in one vertebral body, common but rarely give symptoms; x-ray shows coarse trabeculation.
5. Dermoids, in connection with spina bifida occulta.

Primary Malignant Tumors

1. Fibrosarcoma—resembles Pott's disease, but there is more rapid destruction.
2. Endothelioma—this shows hematogenous metastases.
3. Multiple myelomas—these are recognized by plasma cells in a marrow biopsy, Bence Jones protein in the urine, and x-ray showing collapse of the vertebral bodies.

Metastatic Malignant Tumors

1. Carcinomas—there is gradual erosion of vertebrae with collapse.

2. Sarcomas—the erosion is more rapid.
3. Multiple myelomas.

The treatment of malignant tumors is symptomatic. Occasionally mechanical or operative support is indicated. Chordotomy is occasionally used to relieve severe pain.

Pain—Cont'd

- in acute appendicitis, 684, 685, 686, 687, 924
- cholecystitis, 927
- pancreatic necrosis, treatment, 631
- pancreatitis, 918, 928
- of angina pectoris, 523, 524
- anginal, in coronary artery heart disease, 530
- back, 1245
- in carcinoma of colon, 705
- of pancreas, 638
- change of position causing accentuation or relief, 913
- chest, types of, 441
- in feet due to cold injuries, 143
- in gall bladder disease, 608
- in kidney tumors, 857
- location sequence, 910
- in lower extremities in arteriosclerosis obliterans, 953, 954
- osteoarthritis of hip, 1155
- osteogenic sarcoma, 1236
- due to pelvic disease, 729
- in peptic ulcer, 563-566
- in perforated ulcer, 917, 918
- postoperative, 108
- rebound, in abdomen, 913
- referred to shoulder from diaphragm, 914
- in region of heel, 1203-1204
- as symptom of esophageal disease, 540
- in thrombophlebitis, 986
- Palate, cleft (*see* Cleft palate)
- muscles, 241
- Palliative resection in carcinoma of stomach, 578
- Pallor in anesthesia, 173
- Palmar avulsions, hand injuries, 1126
- spaces, hand, infection, 1111-1112
- Palpation of abdomen in diagnosis of acute conditions, 912
- of arteries of lower extremity, technique, 953
- of fistula-in-ano, 716
- of knee, 1165
- of neck, 352, 353
- of oral cavity, 325
- rectal, of pelvic peritoneum, 918
- of thyroid gland, 389
- Palsy, facial, 234-236, 380
- lower radicular, 310
- upper radicular, 310
- Pancoast syndrome, 471
- Pancreas, 620-639
- aberrant tissue, 622
- acute conditions of, diagnosis, 928
- anatomy, 620, 621
- annular, 622
- blood supply, 620
- carcinoma, 638-639
- cysts, 636-637
- developmental anomalies, 622
- ducts, anatomy, 620, 621
- embryology, 620

Pancreas—Cont'd

- injuries, 628
- islet cell tumors, 409-411
- lymphatic drainage, 620
- nerve supply, 620
- physiology, 621
- stones, 636
- surgery of, history, 9
- tumors, 637-639
- Pancreatic cysts, x-ray diagnosis of, 628
- ductal system, visualization of, 627
- enzymes in peritoneal exudate, 623
- lithiasis, 636
- necrosis, etiology, 629
- rests of small intestine, 582
- secretion, control of, in acute pancreatic necrosis, 632
- Pancreatitis, acute, 628-634
- clinical features, 630
- complications, 634
- correction of secondary metabolic derangements, 633
- diagnosis, 928
- differentiated from cholecystitis, 607, 928
- from perforated ulcer, 918
- edematous, 630-631
- etiology and pathogenesis, 628
- hemorrhagic, 630
- infectious origin, 629
- lithiasis and calcification in, 627
- noninfectious origin, 629
- serum amylase determination in, 915
- treatment, 631-634
- types, 628
- alcohol in etiology of, 630
- barium studies in diagnosis, 626, 627
- blood count, 624
- carbohydrate metabolism, 624
- chronic, 635-636
- selection of cases for therapy, 636
- specific, 636
- treatment, 635-636
- common channel theory of etiology, 629
- duodenal drainage in diagnosis, 625
- enzymes in blood, 622
- in urine, 623
- gall bladder disease associated with, 629
- hemorrhagic, acute, 630
- laboratory diagnosis, 622-628
- serum bilirubin and serum calcium, 623
- stool in, 625
- x-ray examination, 625
- Panels of activity in adrenal cortical function, 402
- Papillary carcinoma of stomach, 575
- Papilledema in increased intracranial pressure, 262
- Papillitis, renal, necrotizing, 866
- Papilloma, benign intracystic, 422 (CP)

Papilloma—Cont'd

- of bladder, 886-887
- of brain, 288
- duct, 422
- of kidney pelvis, 860
- of larynx, 345
- on lip, 331
- of tongue, 336
- villosus, of colon, 702
- Papillomatosis, bladder, 886-887
- duct, 422
- Paraaminosalicylic acid (PAS) in pulmonary tuberculosis, 458
- in tuberculosis of kidney, 876
- Paracolic abscesses, 666
- surgical drainage, 667
- Paradidymis, 902
- Paraduodenal fossae, 776
- hernia, 777
- Paraneuriloma, Hodgkin's, 1004
- Paralysis, facial, 234-236, 278
- third nerve, 262
- Paralytic ileus (*see also* Ileus, adynamic)
- causing obstruction of colon, 925
- complication of appendicitis, 688
- treatment, 680
- Paraphimosis, 896
- Paraplegia, rehabilitation, 304
- Paraplegics, pressure sores, treatment, 227
- Parasite, relationship to host, 36
- Parasitic cysts of liver, 388-389
- Parasympathetic nerve fibers, bladder, 880, 881
- Parathormone, 399
- Parathyroid glands, 399-400
- anatomy, 390
- Paravertebral block anesthesia, 187
- Paré, Ambroise, 3
- Parenchyma, kidney, rupture, 850
- Parenchymatous glossitis, acute, 333
- Parenteral administration of radioactive isotopes, 163
- fluid in surgical patients, 103
- therapy, 782, 783
- Parietal lobe, anatomy, 264
- Paronychia, 1111
- Parotid gland, chronic inflammation, 374
- injuries, 373
- tumors, 375-380
- lymph nodes, anatomy, 371
- region, surgical anatomy, 378-379
- Parotidectomy, diagram, 378-379
- Parotitis, acute suppurative, 373-374
- postoperative, 114
- Parvobacteriaceae, 60-61
- PAS combined with streptomycin, 65
- Pasteur, 5, 36
- Pasteurella multocida, 60
- tularensis, 60
- Patella, anatomy, 1162, 1168
- chondromalacia, 1168-1169
- dislocation, 1169-1170
- fractures, 1168
- recurrent dislocation, mechanism, 1169
- Patellar lesions, 1168 (CP)
- ligaments, rupture, 1170

- Systemic reactions to inflammation and repair, 32-33

T

Tabs dorsalis, destruction of joints in, 1017

diagnosis, 933

Taenia echinococcus, hydatid disease, 588

Talc granuloma, 668

Talipes, definition, 1199

equinovarus, 1199 (CP)

congenital, 1199-1200

nomenclature, 1198

Talus, fractures and dislocations, 1193 (CP)

Tamponade, cardiac, 502, 503

Tantalum¹⁸², 162

Tarry stools in peptic ulcer, 572

Tarsal bones, injuries, 1194

navicular, Köhler's disease, 1204

Tarsus, fractures, 1194

Watson-Jones classification, 1194

Taylor brace, ankylosing spondylitis, 1268, 1271

Technique, surgical, 200-213

Teeth, inflammations, 335

Telangiectasis, hemorrhagic, hereditary, 940

Telecuttherapy, 161

"Teletherapy," 161

Tellurium, bombardment with deuterons, 148

Temperature, body, 33-34

in diagnosis of acute abdominal conditions, 911

maintenance of, in control of shock, 80

skin, rises in arterial disease, 955

Temporal lobe, anatomy, 265

Tendo achillis, rupture, 1186

Tendons, biceps, recurrent dislocation, 1074

rupture, 1074

extensor pollicis longus, rupture, 1098

of foot, lesions, 1185-1187

grafts, 221

of hand, 1107-1108

suture, 1108

results, 1110

synovial sheaths, tuberculosis of, 1116-1118

healing, 1107-1108

repair, 29

suspension for facial paralysis, 235

Tendovaginitis of radial styloid, 1116

Tennis elbow, 1087

Tenosynovitis, 1187

of Achilles tendon, 1204

Tenosynovitis—Cont'd

- appurative, 1113-1114
 - tuberculous, 1116-1118
- Tension pneumothorax, 440
- and hemothorax, 447-448
- Teratomas, cystic and solid, ovarian, 746
- of testicle, 906
- Testicle, contusions, 901
- cryptorchidism, 905
 - inflammations, 901-905
 - malignant tumors, 901 (CP)
 - malposition, 905
 - neuralgia, 905
 - torsion, 901 (CP), 905
 - tuberculosis, 878
 - tumors, 906-907 (*see also* Tumors, testicle)
 - wounds, 904
- Testicular tunics, 902
- Testis(es), congenital anomalies, 902
- ectopic, differentiated from:
 - guinal hernia, 738
 - torsion, diagnosis, 933
 - incomplete descent, 905
 - inflammations (*see* Orchitis)
 - malignant tumors, 906-907
- Testosterone in therapy of breast cancer, 429
- Tests, pulmonary function, 410-441
- and signs in diagnosis of acute abdominal conditions, 914
- Tetanus, 63
- antitoxin, 63, 64
 - toxoid after burns, 128
 - treatment, 63
- Tetany complicating thyroidectomy, 397
- Tetracaine, 184
- Tetracycline with streptomycin in brucellosis, 61
- in tularemia, 60
 - use of, 47
- Tetralogy of Fallot, 498-501
- types of deformity, 498
- Thawing of tissue, inflammatory reaction, 142
- Thecoma of ovary, 746
- Thenar space, hand, infection, 1112
- Theory, practice and, prior to 18th century, 2
- Thermal burns, 121
- Thigh amputations, 1017
- hematoma, 1166-1167
- Thigmotaxis, 27
- Thiopental sodium, history, 4
- Thiopentobarbital (Pentothal), 180
- Third degree burn, 126
- Thomas caliper in fracture of femur, 1160
- splint, 1027
 - test, fixed flexion, 1144 (CP)
 - of hip, 1143
 - walking caliper, 1033
- Thompson operation for cleft lip, 238
- Thoracic aneurysms, 531, 533
- cage, anomalies of, 786-788
 - discs, herniation, 300
 - esophagitis, perforations, 545

Thoracic—Cont'd

- portion of esophagus, anatomy, 537-538
 - rib, first, abnormalities, 994
 - surgery, 434-474 (*see also* Lungs, Thorax; Tuberculosis, pulmonary, surgery)
 - history, 10
 - pulmonary tuberculosis, 457-467
 - vertebrae, anatomy, 1242
- Thoracoplasty failure, 463
- in pulmonary tuberculosis, 463-464
- Thoracotomy, aca of skin preparation, 106
- exploratory, in chest disease, 445
 - in lung cancer, 473
 - in treatment of mitral and aortic stenosis, 521
- Thorax, blast injuries, 451
- congenital anomalies, 445
 - cysts and tumors, 468-474
 - open wounds, 450-451
 - pediatric surgery, 786-790
 - penetrating wounds, 447
 - physiology, 439-440
